Gary,
The Antenna book has 3 verticals in a row. That turns out to be simple. The thing you run into is that many configurations of more than 2 radiators require feeding unequal power to the various radiators.

I think all the stuff in the Handbook uses 1/4 wave antennas over ground. If you use dipoles, all the impedances get doubled. Depending on configuration, that may not be a big deal; in a 50 Ohm system, 70 Ohms is no worse than 35 Ohms.

Tam/WB2TT

According to EZNEC, what you are getting now is slightly less
gain than a dipole with a slightly higher take off angle. To
get very good performance out of that configuration, you are
going to have to learn how to phase the inputs different
from in-phase. That means the two elements will have different
feedpoint impedances thus making it difficult to balance the
currents into the elements.

John wrote:
"To achieve resonance, non-folded dipoles/monopoles must be cut slightly less than 1/2 or 1/4 wave due to "end effect", so I`ve read. EZNEC agrees.

Is this true for the folded dipole/monopole?"

My ARRL Antenna Book (19th edition, page 8) says:

"Since the antenna section (of 300-ohm twin-lead) does not operate as a transmission line, but simply as two wires in parallel, the velocity factor of twin-lead can be ignored in computing the antenna length."

I wish the author had said:

"---the transmission line velocity factor of twin-lead can be ignored---."

Wave velocity on the antenna wire is very important.

End effect is sometimes defined as the capacitive effect at the ends of a 1/2-wave antenna.

Length in free-space wavelengths is reduced in an antenna by a "fat" radiator. The 1/2-wave resonance point (first resonance in an ordinary open-circuit dipole), for a thin radiator, produces a drivepoint resistance of 72 ohms. This can be cut in half by using conductors with a very large periphery. Radiators of large periphery slow the wave velocity along the surface. This reduces the physical length required for electrical resonance.

Feedpoint resistance of the center-fed 1/2-wave dipole results from far-end reflections.In the open-circuit dipole, the high impedance at the ends of the radiators is transformed by the 1/4-wave return to the feedpoint into a low impedance. The short-circuit at the far ends of a 1/2-wave folded dirole is reflected to the drivepoint as a high impedance.

Constructed of the same size wire, a folded dipole has 2 wires effectively in parallel as radiators and their size is enhanced by spacing so that wave velocity is reduced more than in the open-circuit dipole.

The slower the antenna wave velocity, the shorter the length to produce resonance. I would expect more "end effect" in the usual folded dipole / monopole.

Best regards, Richard Harrison, KB5WZI

You already cited one. (You can't apply pressure to a confined fluid if
it's sealed in an incompressible container.)

The phase of the currents in the adjacent sections of twinlead is what is important. If the phase of the adjacent currents is 180 degrees, the twinlead is acting like a transmission line and T-line VF must be taken into account. If the phase of the adjacent currents is zero degrees, the twinlead is acting like an antenna and the VF is considerably higher, essentially equal to insulated wire. If the phase of the adjacent currents is zero degrees, all the current is "common-mode current", something not desirable for transmission lines but something most desirable for antennas since common-mode currents do not inhibit radiation.

Bottom line: The currents flowing in a folded dipole antenna are common-mode currents which radiate, not transmission line currents which do not radiate (much), and that's a very good thing for an antenna.

1518. Feed Through Insulators?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-27 19:25:49 UTC
From: zeno <zeno@sonic.net>
Message-ID: <408EB3BB.6DB24AD@sonic.net>
Source record: 95869

Thinking about getting through walls with ladder line:

1. Would it be better to have the wires proceed continuously to the tuner, without having to make connections at feed through insulators? My understanding, generally, is that the fewer connections the better. This means feeding the ladder line, without break, through the wall(s), something which I can do easily here, but I want to anticipate any arcing etc. and the inevitable moisture in the air during rainy season etc.

2. How should I be conceptualizing the type of RF energy in these lines? I assume that these wires will carry something more like "high voltage" than the usual type of electrical energy in domestic AC lines. How far away should these ladder line wires actually be away from everything as they go through the wall?

3. Fishing through a bucket of old ceramic tube insulators out in the barn I notice most are 3" long, but there are also ones 4", 6", and even 8" long. Seems like using a long one would keep the bare wire of the ladder line insulated pretty well away from the walls which are just wood in this case. Might look odd, having an 8" tube going through a 4" wall, but it would keep the wire of the feed line many more inches away from the wood.

4. Is the issue RF in the ladder line wire arcing to nearby conductivity (eg. moisture on wood)? other than that there is no conductive (metal) material in the vacinity, just wood. I am trying to understand how to be thinking of this RF and how best to insulate going through the wall. Mostly I will run barefoot but might eventually have a 1 KW with a 30L-1.

Source record: 95870

Hi Pat,
Just want to add my 2Cents worth to the discussion.. I use a homebrew Off Center Fed Dipole (Windom is a misnomer , Since a true windham is fed with a single wire line but that's another topic) It works very well But you must use an antenna tuner.. I Use and LDG Z100 with mine and it tunes all bands very well 80--10M. My verison uses a 4:1 balun at the feed point and a Homebrew Choke-- 26 turns 6" diamater just below the balun then another one just before the feedline comes into the shack. the things works very well for me.. without the tuner though the swr on most original ham bands is about 2:1 some less some a little more.
P.S. if you decide to make a homebrew Choke Balun becareful that the Rg8x you use does not have foam insulation.. This type coax will not last long in that application.. because the foam allows the center conductor to migrate to the sheild. eventuall it may even sort out.

hope this is of help.. 73 Dave

I just noticed that these old ceramic tubes fit nicely into 1/2" UV/PVC electrical conduit. I can make this PVC any length I want through the wall and then also fix a ceramic tube into it at both ends for double insulation. That ought to do it.

OK, nice specious argument. You can't have read this far in
the thread without understanding the intended parameters. And since
you seem to be referring to the thermometer, pressure could indeed be
applied. In absolute terms, any container can be compressed, however
slightly. In addition, pressure can be applied without compression by
application of heat or of cold, depending on relative coefficients of
thermal expansion.

Old science class demonstration -- completely fill a heavy
pipe, capping both ends, with a substance; heat the pipe with a torch
and it explodes; toss the pipe into a container of dry ice and it
explodes. What is the mystery substance? It turns out to be water at 4
degrees Centigrade.

Finally, I strongly suspect the "column" of mercury in a
thermometer does indeed obey Pascal's law, but it's effect is
overshadowed by the much stronger effects of temperature and
capillarity.

Is your claim that the height of the column of liquid in a thermometer
determined by the angle of inclination of the column? You were partially
correct in that the barometer is illustrative of Pascals law.

> Old science class demonstration -- completely fill a heavy

True, but not a demonstration of Pascals law.

> Finally, I strongly suspect the "column" of mercury in a
> thermometer does indeed obey Pascal's law, but it's effect is
> overshadowed by the much stronger effects of temperature and
> capillarity.

True, particularly in light of the fact that a good thermometer is
specifically designed to prevent it from demonstrating Pascals law - or
more to the point, from having its measurement dependent upon its
orientation.

As a generalization, sure. As an instance, it will probably never matter. The real question is how can you goof to make it matter?

Obviously by making poor connections [You don't plan to do that do you? You aren't typically shoddy are you? Let's put that nightmare to one side.] There will no doubt be fifteen postings pointing out how lightning "may" melt the connections (and this, of course, presumes many improbabilities equal in likelihood to lightning striking).

Far enough. Flash-over, arcing, and such all derive from the geometry of the gap, barometric pressure, humidity, and such. However, just dredge up a common circumstance of the ordinary Spark Plug and observe the several KV it takes to leap maybe an inch?

You have to work very hard to make it happen - why would it be easier through chance?

However, this doesn't answer the question so much as offer perspective. Keep the ladder line as far away from anything (fill in the blank) as it is wide. If you want, double that value for a safety factor of two. If it won't arc across the lines, it sure won't jump to the wall out of caprice.

SWR is a manifestation of literal Standing Waves that in turn exhibit voltage peaks and current peaks distributed along the line between the line leads. If you are so lucky as to have a balanced load (which thus offers a minimum of common mode potentials), it stands to reason you've confined your risk. Bringing nearby conductive elements into the scheme introduces both an unbalance with a corresponding rise of common modality. Would you hold a nail between the conductors?
Recent suggestions that little matters over the short haul mock your sensibility to this question. Sparks occur at site dislocalities and drawing down wide spaced, paired lines to fit through a small hole are classic spark generators (anyone every see a jacob's ladder?). Same thing goes for the impedance bump of a dielectric (your wall) introduced between them coming through separate holes. In short, jeopardy either way.

Which scenario offers more path resistance? There is no better determiner of success. Your ceramics were made to answer that. Basically, (and on the basis of what you have written thus far) trust your instincts and then test.

The question is simply: how much potential resides between the two leads at any site dislocality? Change the frequency and you have to answer that question again. Are those holes bridging (AKA shorting) a voltage maxima, or voltage minima of the Standing Wave? If you know that answer, then apply that knowledge to every half wave interval along the line all the way to (and including) the antenna and ask: is there something nearby each or any of those points that will catch a spark and render a flame?

Gary,

How did that transparent plastic insulation on the monster cable wire hold up in the sunshine over the years? I am thinking that if it decays and cracks it might have an effect on the way the wire is fastened to the spacers and thus come loose from the spacers.

I do have quite of bit of this #12 monster cable left over on a spool from a speaker project I did last year. Also this monster cable is relatively expensive compared to other alternatives and I would almost hate to use it for feedline if it would only hold up a couple of years in the weather and sun. I wonder just how much this monster cable braided copper differs from regular #12 braided copper for AC wiring? Seems like maybe the individual strands in the monster cable are finer than the ones comprising regular AC braided wire of the same guage.

Cecil, W6DXP wrote:
"Bottom line: The currents flowing in a folded dipole are common-mode currents which radiate, not transmission line currents which do not radiate (much), and that`s a very good thing for an antenna."

Nicely said! Agreed that it is the common-mode currents which radiate, but differential-mode currents exist too. At the tips of the folded dipole, some current turns the corner and flows in the opposite direction after its U-turn. This creates a situation much like the reflection from the open circuit ends of the common dipole. At the center of the continuous wire which ties the tips of the driven side of the folded dipole together, the colliding currents have traveled the same distance at the same velocity so they are still 180-degrees out-of-phase. This amounts to a short-circuit, and in fact this amounts to a zero voltage point which may be grounded without consequences in most cases.

In the folded monopole (unipole), the currents into the input terminals flow nearly as they would flow into any 1/4-wave short-circuit stub. The difference seems to be that the grounded side of the transmission line feeds both its side of the folded unipole and the ground plane, creating an opportunity for imbalance and radiation. And, radiate it does with very nearly the same characteristics as an open-circuit ground plane antenna.

Ouch, Richard, that's a pretty wild shot from the hip. Spark plugs
use gaps on the order of hundredths of an inch and voltages
on the order of dozens of KV.

And for Zeno, just bring the tube out to the surface of
the wall, don't extend it... you don't want those things
breaking off!

"Thinking about getting through walls with ladder line."

I`ve brought open wire lines through walls by Pyrex bowl insulators mounted on a sheet of plywood framed into the wall as if it were a window. The plywood between the conductors seemed not to hurt. Glass or Plexiglas would be better and might obviate the bowl insulators.

You also could cut the plywood, Plexiglas, or glass sheet to fit under a window sash. Then, just lower the sash on the sheet.

You want innocuous materials between the wires and surrounding the line by at least several times the spacing between the wires.

1534. really long control cable on a screwdriver

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 03:52:17 UTC
From: Jeremy Salch <salchNOSPAM@tblx.net>
Message-ID: <c6n9re$dmc70$1@ID-225834.news.uni-berlin.de>
Source record: 95885

I'm using a KJ7U,www.kj7u.com, screwdriver antenna and its "control cable", for lack of a better term, is around 60 feet long. At this length it seems to be causing tuneing problems.

It appears that the cable is trying to radiate and thus it causes the SWR to rise above what it should be. The best way I can validate this is to tune it the best I can then go unplug the cable from the antenna. When I do this the SWR drops down to around 1.1 or so. Otherwise on some bands it is as high as 3 - 4

I put some toriod? cores on the line which helped out the problem on 80m to some extent. It did help bring the swr back down to a more acceptable level, but it still isn't as low as it is when the cable is unplugged.

When I had this antenna mounted in a different location and the cable was considerable shorter, none of this seemed to happen.

Anyone have any ideas or experiences with something like this ?

I have absolutely no experience with analyzing a folded dipole. I would like to take advantage of this thread to ask for some information.
I had thought of a folded dipole as an antenna with a pair of 1/4 wave shorted stubs across its feed point. I thought the antenna length for a 1/2 wave dipole would be the same if it was fed as a 72 ohm dipole or fed as a 300 ohm folded dipole. But, if there was some dielectric loading in the twin lead it would make it necessary to account for the VP of the twin lead used for the *folded dipole" so the impedance of the stubs would be accounted for.

Specifically -- If a 1/2 wave folded dipole an antenna is constructed with a twin lead with a VP of 0.9, and the total antenna length is close to 1/2 wave, the shorted stubs will impose a capacitive reactance shunting the feed point impedance.
But, when I take my thinking to extreme configurations, my ideas seem to fail.

I'd sure like to get some "real life" data. I'm sure some of you guys know if the real life folded dipole gets measurably effected by VPs of 0.8 or 0.9.

Sorry you got bit there, Stephen,

It's called understatement. Besides, RF potentials have the capacity
to excite conduction above and beyond ignition spark conditions.
However, all things considered, the general breakdown tabulations
illustrate it remains fairly difficult to accomplish.

Hi Jerry,

Well, I presume you've corresponded here enough to recognize the
answers to questions fit what the respondent chooses.

Open EZNEC;
Select the "Open" button that is at the top left of the application;
Select the W8JK.EZ design offered;
From the string of ">" selections, choose "Plot Type";
then select "3 Dimensional" - "OK" (and respond "OK" again to prompt);
Finally select the "FF Plot" button at the bottom left.

This will generate an X-Y-Z plot of the radiation lobes of this
particular antenna design. Clicking and scrolling your mouse over the
image will roll and rotate it to allow you to shift perspective. The
antenna element spacing is closer than your quarter wave (0.1 in
fact), but it gives you a basis to change things and see what happens.

This means you can introduce your self to the Wires table (select the
">" which is labeled "Wires"). Change something and then look at the
antenna (select the Button labeled "View Ant"). To see how your
change impacts transmission lobes, select that same button "FF Plot."
The Wires table is based on simple XYZ co-ordinates for each end of a
wire (segments is an artifice of necessity for the computation engine,
once you've laid out the basic form, we can come back to that later).

Instead of worrying about clunky transmission lines, you simply
replace them with "Sources" that take their place (this antenna has
two of them to represent the split feed). You can be anal and build
them out of virtual transmission lines, but give yourself a break and
ignore that; it is hardly instructive for the first pass.

Welcome to the world of modeling. Press more buttons and appreciate
the scope of data available for analysis. Return to the "Open"
button, and appreciate the variety of simple designs that offer a
fairly broad selection of styles. The free version allows quite a
latitude of variation, enough to educate you in all the fundamentals
of both design and the application.

Jerry Martes wrote:
"I`d sure like to get some "real life" data."

Personal experience testimonials are often unreliable. Modeling data are often more complete, skillfully designed, well executed, and less colored by the operator`s opinion, by the right modeler.

One highly educated, experienced, and competent source is L.B. Cebik, W4RNL. The plain folded dipole is just one of the many antenna types he has modeled and enriched his web pages with. He compares it with the common open-circuit single wire dipole in his analysis.

Just search on "folded dipole". Cebik`s web pages will appear near the top of your list of options. Click on the most likely of your options and you are there.

Thanks Richard

I printed your post. I'll try to learn how to use that antenna modeling program. I am amazed at how engineers have gotten so smart these past few years. It seems impossible that anyone could get smart enough to do something this complex that it models antenna patterns almost immediately.

It will sure be satisfying to become able to use this program.

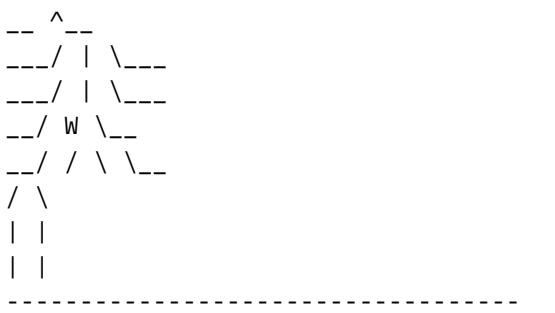
1542. How to model the house

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 11:04:09 UTC
From: Jon Kåre Hellan <dev@null.com>
Message-ID: <ter7u88ity.fsf@persaunet.uninett.no>
Source record: 95893

I've read a lot about modeling antennas and ground. But what about the house? Dipole configurations might look like this.

Or this

Or even this



(ASCII art looks better in a monospace font)

The house probably makes a lot of difference to gain and pattern, and also for other antenna types.

Modeling the house as part of ground might make sense, but there will be lots of differences. Metal roof and sidings would turn the house into a faraday cage. A wood frame house with no wiring and plumbing may be almost like air.

Has anybody included buildings in their models, and have they checked
if this made the model more realistic. Any rule of thumb parameters?

Jon Kï¿½re - LA4RT

1543. Re: Carolina Windom Problem...any suggestions

Don't forget to check your coax and connectors.

1544. Re: really long control cable on a screwdriver

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 12:33:56 UTC
From: 'Doc <w5lz@cwis.net>
Message-ID: <408FA4B4.366A21A2@cwis.net>
Source record: 95895

Jeremy,
Hmm, sounds 'reasonable' to me. A 60' control cable
is about 1/4 wave on 80 meters, and if you're using the
antenna on 80 meters, well...?
'Doc

PS - Sort'a suprised it hasn't singed your mustache, LOL.

1545. Re: Feed Through Insulators?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 13:02:29 UTC
From: 'Doc <w5lz@cwis.net>
Message-ID: <408FAB65.AA658B82@cwis.net>
Source record: 95896

Bill,
If you have the insulators and want to use them, why
not? Even if you have the insulators and you don't want
to use them, no problem there either. The 'dislocality',
'discontinuity', impedance 'speed bump' where the ladder
line goes through the wall just isn't going to make a lot
of difference. It would just make sense to use some kind
of nonconductive material imediately around the feed line,
but going way out of your way to do so seems a bit
excessive (all things considered). I've seen ladder line
fed through an under-eave vent, routed through an attic,
laying on 'stuff', and then through a sheet rock ceiling
via a 'slit' cut with a knife. No problems with matching
or high voltage arcing even at legal limit power levels.
As for 'connections'. Make them even 'close' to right
and there should be no problems with arcing. If you're
really worried about it, stagger the connections. I've
seen some really 'fubar' installations, but never any
arcing of the ladder line, yet... Metal backed insulation
would be my biggest 'worry, but even that wouldn't cause
any loss of sleep...
'Doc

Hi,

I do not know nobody who has included the building in the formula. It should be interesting to get a report about it and I should be curious to get the opinion of a telecom engineer or to see any radiation pattern with/without building included.

Possible configurations are of course infinite. You can always replace any object, car, house, etc, by a special configuration of selfs and caps. Harder is to find the correct values... The only solution is to experiment in the field with a meter as two house are never built the same way.

All depend first of the working frequency and then of the height of the antenna above the object.
Over 1/6 lambda or so over/away from the house I am not sure that the object will much influence your radiation pattern. Theoretically it does, in practice this is another affair : could you hear this difference ?...
Then there is the problem of radiations transmitted by your home devices too, from TV to boilder, TL and other old remote controller that could surely more bothering that your "house" seen as a whole as they can transmit RFI at some frequencies in ham bands.

Even with a dipole placed in inverted V the high point on top of the chimney, the wire tilted at 45 deg like this,

```
!chimney
/ !
wire/ ! house wall
```

I know many OM that get excellent results, even in pile-ups (with patience) as the antenna is somewhat directive and help a bit. They do not care about the pattern, they practice, and they see that their "small antenna" perform well. All the more when we know that this is the first third of the antenna (close to the center feed point and thus from the chimney) that radiates and much less the ends.

On the other side I know some OM that have erected their beam over apple/cherry trees, they have never complained about any loss of power or difficulties to work any entity.

If the problem exists well, its influence must be relativised.

Hi,

As usual the longer the best... I experimented a 6, 8, and a bit long vertical with a maximum of 2 traps (for the smallest), the longer, a Cushcraft, get the best result in DXing.

I think that there is no secret:
- you need either a good ground if placed at ground level
- some counterpoise if it is placed in elevation (the highest the best)
- a good length (lamda/4, 5/8 or 1/2) compatible with your working frequency.

In fact you need to apply the law of physics never the ones of marketing...

Not that simple, like siding, is it RF connection tight or insulated slabs? Millions of other questions, like you AC wiring, plumbing, coathangers, etc. If you manage to model it, what are you going to do about it? Level it? :-)

We know houses are bad for antennas, sources of distortion and interference from and to. If you are serious about serious antennas, you keep them away from the houses. If you worry about dipole over the house, don't. Just put it up and enjoy it. Modeling it won't help anything.

Modeling mobile antenna over particular type of vehicle can give us clues about efficiency and pattern, but measuring it will be more accurate, consider the current distribution in the loading coil and other effects in a real life time.

So if you worry about Inv Vee or dipole, just keep the ends as far away from your appliances to minimize the RFI TVI. On HF don't worry about stupid silly and irrelevant "RF Exposure Guidlines" on HF with typical ham setup.

Remember the President's words after 9-11.

His definition of 'terrorist' is VERY V E R Y large. It includes the terrorists themselves, the people who finance them, the governments who finance them, those who shelter them, those who train them, those who provide logistics for them, those who provide sanctuary for them, those governments that are not actively working to eliminate them, etc. It is so broad that it can be understood as: "If you're not actively working against terrorist/terrorism, then YOU are a TERRORIST." [Saddam allegedly paid $25,000 to the families of Palestinian suicide bombers.] Today's terrorists operate in a supranational environment, above the normal understanding of national government. In our terms they are a NGIO, a Non-Governmental International Organization.

If you believe that there are no terrorists in Fallujah then no argument or statement of facts will convince you.

Remember, approximately 1000 years ago militant Islam and militant Christianity engaged in a 200 year war to contain militant Islam. Militant Islam is not dead. It has been dormant for many years.

In the modern context, it seems that today's terrorists are, in the majority, militants from an Islamic background. Having said that, it is not to be understood that the vast majority of those who claim Islam as their faith are terrorists. Likewise, those who claim Christianity as their faith are not war-mongers, although many Christians are in the military.

There was no leader more secular in the Middle East than Saddam. I'm not saying he was a good guy, but he had nothing to gain by assisting Al Qaida, who, broad as you might want the terrorist definition to be, were the people directly responsible for the events you referenced. Don't blur the goal. Even Bush said there was no connection between Iraq and Al Qaida. On the list of priorities, as far as battling terrorism, Iraq should've been at the bottom. It would've made more sense to bomb Mexico. Saudi Arabia has financed, and still finances, more extreme fanatics than any other country yet is considered a staunch ally.

Ms. Karin Hughes, one of Bush's primary advisors, referred to the pro-choice rallying people this weekend as "terrorists". Should we give them a little shock and awe too?

Called a self-fulfilling prophesy.

6,000,000 Cambodians weren't suffering terrorism by our definition
when they were massacred. No Christians to speak of, nor oil in
Cambodia.

1,000,000 Tutsis and Hutus weren't suffering terrorism by our
definition when they were massacred. No Christians to speak of, nor
oil in Rawanda.

Tribal warlords in Afghanistan (our allies) practice rape and force
women into prostitution, they support 90% of the world's Heroin trade,
but at least they are not terrorists by our definition (not nearly the
satan of Noriega in Panama who knew to many deals cut by Bush elder).

We nearly bought into the European definition of no terrorism in the
Balkans. No Christians to speak of (mostly Moslem), nor oil there,
but Gen. Clark didn't use that as an arbiter of morality.

I went to hear Ariana Huffington speak last night here in town.
Someone offered her a profound observation:
"Don't believe everything you think."

Sage advice.

One of the best guides to vertical antennas for the ham is chapter 9 of ON4UN`s "Low-Band DXing", published by the ARRL.

ON4UN lists equipment used by some of the best known DXers, but antennas are listed only by types, not brand names.

ON4UN`s book is probably available in most countries.

Hi Bill

The monster cable I had was ultra fine stranded to about size #8 copper, very thick.
It was only 8 years that it was up before I moved, and in that time it did not get brittle although it did change from clear to amber over that timespan.
I was able to roll it up and bring it with me and saw no signs of cracking. But even if the insulation came off completely, it wouldn't affect it as far as ladder line goes. I was even thinking of stripping the insulation before using it for ladder line, but it was somehow molded onto the wire braid which would make stripping it quite hard. So I used it as is.

FWIW: My son who is a Hi Fi buff, is now using something similar in appearance to our RG8U but in a twin housing, like some twin Cable TV cable. I have no idea of the impedance or actually what it is he is using. But he seems to like it better than the Monster Cable.

I have a severly limited capacity for understanding alot of theoritical presentations. I did read some of Cebik's information, and I still wonder if the velocity of propagation of the "twin lead" used for the folded dipole can be ignored. I wonder if the VP of the twin lead is an important consideration when designing a folded dipole.
If the resonant frequency of a folded dipole is identified as that frequency where the input (feed point) impedance is R+/-j0, it seems that the 1/4 wave stubs that shunt the feed point might strongly effect the input impedance.
I recognize that there is a good chance that my reasoning is wrong. It may be that the "stubs" that I consider to be shunting the fed point, are not acting the same as a 'non disipative' stub. But, this is where my mind could benefit from having some "lab data" which is what I refer to as "real life" data.

Maybe use some capacitors from the control wires to ground to short out the rf right to ground before it gets to the toroids. The toroids then won't have so much rf to work with and they may not be as likely to saturate.

Be careful with the capacitors that you get transmitting style that can handle a good amount of rf current.

I'll try putting them at different locations along the cable. I have 4 that
are designed to clip onto wire the size of rg-8u so I coiled up the
control cable and cliped the cores over the coil of wire, and i put all 4
on that coil. I'll try making several smaller coils and putting them at
different places along the cable

Not at the resonant frequency.

Don`t sweat twin lead VF in an antenna as radiation is from common-mode current.

The marvelous 19th edition of the ARRL Antenna Book has Fig 17 on page 24-14. It`s "Lumped-constant circuit equivalents of open and short-circuited transmission lines". Note (A), the top figure, which is a short-circuited stub of any length less than 1/4 wavelength. It is an inductance! Also note (C). It is a short-circuited stub of exactly 1/4-wave:

Equal to a parallel resonant circuit, a "very high" impedance. So high in fact that many in parallel would not be noticed.

Best regards, Richard Harrison, KB5WZI

I've heard of doing this before, with the capacitors, so would this be the
ceramic type? and how would i distinguish between "transmitting" style and
regular capacitors?

The VF of twin-lead used for a folded dipole is approximately the same
as the VF of insulated wire used for a dipole. I'm just not sure how
much "end effect" actually exists in a folded dipole since there is,
technically, no end.

> If the resonant frequency of a folded dipole is identified as that
> frequency where the input (feed point) impedance is R+/-j0, it seems that
> the 1/4 wave stubs that shunt the feed point might strongly effect the input

There seems to be some confusion about exactly how the feedline connects
to the folded dipole. Here is the correct way:

```
+-----------------------------------------------------------------+
| |
+-------------------------------+ +-------------------------------+
| |
| |
```

Here is the incorrect way:

```
|
|
+-------------------------------+-------------------------------+
| |
+-------------------------------+-------------------------------+
|
|
```

For the incorrect way, the feedline is indeed seeing two shorted 1/4WL
stubs in parallel. The currents for the incorrect way would be 180 deg
out of phase and defeat the purpose of the antenna.

However, for the correct way, the currents in the adjacent wires are
in phase and there is a current phase reversal (current minimum point) at
each end of the antenna. After all, a folded dipole is just a one-wavelength
loop with the conductors brought close together. When Mr. Moore invented
the Quad beam, he envisioned a folded dipole with its conductors being
separated incrementally by a distance until it came out to be a square.

The key to understanding the folded dipole is that there is an electrical
phase reversal at the same point as a physical 180 degree reversal.
180 + 180 = 360 degrees, i.e. in phase.

A classic stub is a current-balanced device with the currents 180 degrees out
of phase. That is not true for a folded dipole antenna. Therefore, a folded
dipole antenna is not composed of true stubs. Semantics strikes again. A series
"stub" is different enough from a parallel "stub" that we probably should not
use the same word for the two of them.

1568. Re: End Effect on folded dipoles/monopoles?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 18:46:35 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <108vv0g4u9mcha7@corp.supernews.com>
Source record: 95819

The currents in the wires of a folded dipole or monopole are neither in phase nor 180 degrees out of phase, as you can easily see from EZNEC. Because they obey superposition, you can, for convenience, consider them as two separate sets of currents, common mode (or "antenna" current) and one differential mode (or "transmission line" current). Neither one is zero. The phase of the antenna current is a function of the velocity factor of the two wires excited in parallel. For TV twinlead, for example, this would be something like 3 percent slower than for bare wire -- about the same as any other typical insulated wire. In contrast, the phase of the transmission line current is dictated by the velocity factor of the two wires excited out of phase as a transmission line. In this mode, there's an intense field between the conductors, so the dielectric between the conductors has much more impact. The velocity factor for this mode is more like 0.8, so the transmission line will be electrically considerably longer than a quarter wavelength.

The TV twinlead "antenna" will be resonant, then, at a length about 3% shorter than if it were made from two parallel bare wires -- not because the currents in the two wires are in phase, but because the common mode part of the currents are in phase -- by definition, in fact. But the effect of the transmission line stub also affects the feedpoint impedance, and its velocity factor has to be accounted for in the calculation of its contribution. I've seen a recommendation that the conductors of a twinlead folded dipole be shorted about 80% of the way from the center. What this does is to make the transmission line nearly a quarter wavelength long, so its contribution to the feedpoint impedance is negligible. Then you don't need to make any adjustment of the length to compensate for the transmission line. Alternatively, you can short circuit the wires at the ends in the normal fashion, and slightly adjust the length to compensate for the impedance change caused by the transmission line.

1569. Re: Carolina Windom Problem...any suggestions

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 18:50:50 UTC
From: Larry <nospam@REMOVEME.com>
Message-ID: <e2Tjc.16334$e4.1061@newsread2.news.pas.earthlink.net>
Source record: 95820

My experience with a Radio Works Carolina Windom 160 special with 75' of RG-8x lead is as follows. The antenna is mounted 50' off of the ground. The "special" antenna is the same as the Windom 80 (133' long) but the balun and isolator are wideband to cover 160. I bought it with the insulated #12, 259 strand option.

The supplier states that you need to be able to tune for VSWR up to 10:1. Most built-in tuners will not handle that range. My Ten-Tec Jupiter w/autotuner does.
Measured average VSWR per band w/o tuner is below:
160 9.3:1
75 4.3:1
60 5.8:1
40 4.3:1
20 2.4:1
17 3.1:1
15 2.6:1
12 1.3:1
10 2.6:1

Except for 160, the VSWR variation across a band is less than +/- 0.5. The high end of 160 is about 7:1 and the low end about 12:1. Except for 160, the tuner brings it to 1.0:0. The beauty is, once I tune a frequency in a band, I do not tune again while I'm in the band.

As far as azimuth pattern goes, the density of contacts pretty much tracks where I expect the stations to be most dense. So, I would guess the pattern is somewhat close to omni as the supplier claims. It appears to have good low angle radiation since I have made numerous contacts at 4000+ miles with my 100 W PEP SSB. I have only had the antenna (and my ticket) for less than a month. I have made no contacts on 160 (only tried twice) 15 to 10 have been dead and I really haven't tried. 75 through 17 have been rewarding.

Hi Jeremy,

There should be no distinction between caps for this job - almost
anything will work as the control voltages are so low that even
dielectric breakdown is unlikely.

On the other hand, the package style may be more carefully considered.
The high end designs use what are called "feed-thru" button styles
that are designed for bulkhead connections with a pig-tail on either
side and the cap looks like a threaded stud with a collar. These are
specifically designed to decouple rf off of dc lines. They provide
the shortest lowest inductance path to ground (essentially zero lead
length).

These would be a must for UHF, but at HF you are just as well off with
simple, leaded Micas, Ceramics, Paper-oil, polystyrene, tantalum, or
any of a host of others. You don't really want massive capacitance
(which is to say perhaps tantalums and like are unnecessary overkill)
because 10,000pF is more than enough but 0.22mF works just as well.
If you assist the cap with a small choke (on the noisy side of the
current) you gain that much more isolation. Again, any value is
better than none (but it hardly begs 1H audio chokes).

"Stub" has more than one meaning and therefore, more than one response.

Your definition of "stub" seems to assume the currents are 180 degrees
out of phase. Therefore, you should not use the word "stub" on a folded
dipole antenna where the currents are in phase.

It's a semantics problem. If you revise your definition of "stub" to
include stubs with in phase currents, you must give up on your present
definition of stubs with only out of phase currents.

Most of us have a feel for the difference between a parallel stub
fed from a line with balanced currents and a series stub where the
currents can have any phase relationship. "Series stubs" is a very
confusing topic and could support a technical article of some kind.
I don't remember it ever being explained in detail before, at least
in the amateur literature.

Hi Jon,

This is actually far simpler than others would have us believe.

Model the antenna you have above/near the house. Model it in the
conventional way (no house) while taking care to include the usual
loss (copper loss, ground loss).

Now measure your antenna's characteristics.

Subtract Measured results from Modeled results = House effects

There's your model for the future. And it's accurate. This beats all
the tea leaf reading and gazing into Xtal Balls to achieve a mystic
answer.

> the details of which I don't know.

Pascals law, just as any other natural law, always remains in effect. The point is simply that a sealed column of liquid will NOT change length by a factor of the square root of two at an inclination of 45 degrees. That was initially my issue with Cecil.

A barometer on the other hand is obviously not sealed. The weight of the column of mercury is balanced against the weight of the atmosphere acting on an open reservoir of mercury at the bottom of the column. The reservoir will act to maintain the column at a constant vertical height by adjusting the length of the column as a funtion of tilt angle. A sealed column does not act that way.

I disagree that it's specious to point out that rather significant and fundamental difference.

Somebody at www.coxar.pwp.blueyonder.co.uk probably deserves the "credit". What Feeling Lucky does is automatically link you to the first hit on the search results list. I saw the Google guy on CNBC a couple months ago and he was asked about it.

Roy

Thanks for the clear and meaningfull response to my post. I'm not qualified to enter this discussion. I'm in the learning mode. I did wonder if the dielectricly loaded "shorted stub" transmission line (1/2 the folded dipole) wuld have a shortning capability for determining antenna length. As I read it, the VP of the twin lead does effect the folded dipole's length to aceive resonance. And, the amount of "shortning effect" is somewhere between 20 percent and 3 percent in your example of twin lead with VP=0.8 .Please correct me if I'm wrong, but, I'd expect the "shortning effect" to be much closer to the 3 percent end of the scale for reasons that would be too confusing for me to try to explain. (besides, I'm probably wrong in my thinking)

Source record: 95830

When the transmission line portion is nearly a quarter wavelength long, it has very little effect on the feedpoint impedance, so the resonant length will be about the same as it would be if the transmission line didn't exist. In the case of TV twinlead, though, if shorted at the ends, the transmission line can make a noticeable impact on the feedpoint impedance. It would take only a few minutes with EZNEC, using the method I described earlier of modeling a folded dipole or monopole as an unfolded dipole or monopole with a transmission line stub in parallel with the source, to see how great the impact is. With this model, you can give the transmission line whatever velocity factor or length you choose, independently of the "antenna" portion of the model. If you use the same twinlead to make antennas for different bands, the impact of the transmission line will be different on each band because the transmission line isn't being scaled with frequency. Therefore, any conclusion you reach about the impact of the transmission line on the antenna length will be quantitatively correct only at one frequency (and, of course, only the assumed type of twinlead).

I don't have the time right now to do the modeling, but if you're truly interested, you won't mind taking the time to do it yourself.

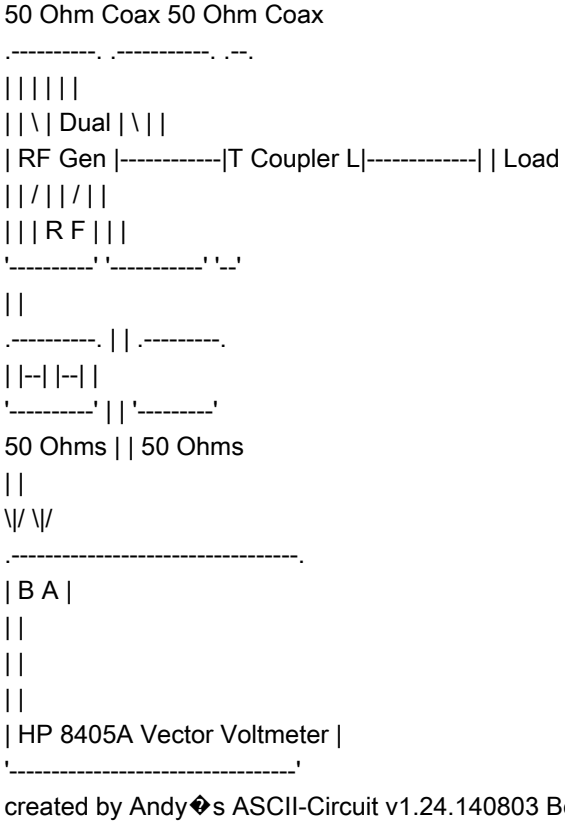
1580. Measure Z with Vector Voltmeter properly

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-28 22:18:19 UTC
From: The other John Smith <jocjo-john@yooha.com>
Message-ID: <L4Wjc.13394$eZ5.4583@newsread1.news.pas.earthlink.net>
Source record: 95831

I now have an HP 8405A Vector Voltmeter. I also have a Narda dual directional coupler. Here is how I plan to set up and measure things at about 440 MHz (antennas, etc) so I can determine their impedance (view in fixed-width font):



T is the transmitter port, L is the load port, F is the -30 dB forward coupled port, and R is the -30 dB reverse coupled port.

The HP voltmeter is able to zero out the phase angle between channels A and B. So, I'll put a 50 Ohm dummy load out there for the Load and set the phase angle offset to zero.

Then I'll put the actual load out there for the Load and read the channel A voltage, the channel B voltage, and the phase angle between them.

Then I'll calculate the impedance with:

Z = 50(1+Er/Ef)/(1-Er/Ef)

where Ef is the forward voltage and Er is the reflected voltage.

For my tests, I will assume the coax really is 50 Ohms and non-reactive. Since A is the reference, it will appear to be a real number. Ef will be a complex number.

I'm not looking extreme accuracy. About plus or minus 10 to 15 percent will be acceptable. Will this work? Your thoughts and advice will be appreciated.

Thanks,
John

35,000 lives saved huh. That is one person's opinion....not mine.
Actually 711 Americans and counting are dead because of Bush's
careless decision to go to war with Iraq. I COULDN'T CARE LESS
how many more arabs are dead.... I care about Americans. The arabs
are going to have to figure things out on their own.
Bush attacked the wrong enemy. He has created a problem where none
existed before. Al Q. was not in Iraq before Bush toppled Hussein. But
they are sure there not and recruitment is up sharply. Its too easy to send
other American's kids to fight a war. Bet none of your kids are over there.
I'd LOVE to send Bush's priviledged daughters over there.
Actually my knowledge on current events is good..... better than yours
I'd be
willing to bet.

Hello,

I am working on a PCB-based antenna, with copper on both sides. Believe it or not, the hardest part is figuring out how much the PCB material would cost. Does anyone have any PCB costing numbers for FR4, FR408, Nelco 40013, Rogers 4003, any other material? I understand that thickness plays a major part in the cost so if possible please include the board thickness with the cost number (I am currently thinking of using 20mils thick PCB). It would probably be easiest if the cost was in units of US$ per sq. inch or sq. cm. Many thanks.

Roy

I'm honored that you take time to post this information for my education. It is almost an unbeleivable coincidence that _you_ mention EZNEC. I had that program recommended to me by a friend who told me about it this past week end. I want to try to understand (see) what kind of pattern I'm getting from an antenna I made for Weather Sattelite (137 MHz) reception. I have downloaded the EZNEC and only my other projects have kept me from starting to learn how to use it.

Thanks
Jerry

No he is not making fun of you. There is a style of capacitor that is called a door knob for the shape that it is made in.

To start out with go ahead and try some good high voltage ceramic capacitors from the control lines to ground. A fairly high value of 0.47 uF might do good in parallel with a .01 uF cap.

For the toroids in the line they have to be fairly hefty as there could be some significant currents running on the lines at the different frequencies. If the toroids saturate they won't work as intended and can cause some real interesting things to happen.

Hi John,

The topology is good, however there is work to do to justify your confidence in the numbers (even if you are willing to discount them to 10 to 15%; which, by the way, is quite optimistic).

I presume you have three 50 Ohm loads, or so I am lead to believe by the nature of your description. If so, it would do well to rotate them all through each port and confirm NOTHING changes. This is no simple expectation. It also pays immensely to have calibrated mismatch loads on hand to confirm your measurements of an unknown (the system may fail unbeknownst to you otherwise).

Further, you should also swap the dual coupler input/output and the side arm ports to confirm it is in fact operating at fixed ratio (this says nothing of the presumed ratio, but is still a necessary step). Then repeat the paragraph above concerning the 50 Ohm load rotation. You can then proceed to confirming the coupling coefficient which may surprise you (you haven't given the pedigree of this particular beastie).

I presume you have undamaged leads for your meter (I won't even presume they are calibrated, but for these purposes, testing should reveal problems if they are not sufficient to the task).

I presume your source is powerful enough to present at least 1mV of RF to the meter. I know the meter is more sensitive, but you need head room to simple measure the return loss (or Z or SWR or any derived characteristic).

I presume your source is free of spurs and harmonics at that power. It hardly is worth the effort to measure out of band products.

I presume your source will not pull when presented with a large mismatch.

I presume your source offers a 50 Ohm output Z. There is nothing like a mismatched source looking at a mismatched load to increase confusion by the square.

So, sure, it'll be a snap. ;-)

Hi Pat,

I was originally looking at a Carolina Windom and one of the vendor's comments to me on a phone call was that the vertical section had to be at least 15 feet from any metal (i.e. a tower or metal support mast). This was not practical for me so I dropped the plan - could this be the issue with your setup? Maybe the MFJ has more tolerance!

Just a thought..... Al, VA3KAI

A good tip and one I'll adopt. I do have three 50 Ohm loads. I don't have mismatched loads, but I can parallel 50 Ohm loads to make a 25 Ohm load. Come to think of it, 75 and 93 Ohm terminators are available through Mouser. Perhaps I should invest in some.

> Further, you should also swap the dual coupler input/output and the

Yes. I did not mention that I would do that, but my plan was to compare the forward and reverse coupled outputs and record the ratio of the two. I don't think the absolute value of coupling (supposedly -30 dB) is needed for now. The Narda coupler model is not listed at Narda's Web site, so I'm going by the marking on the case.

I have no way of calibrating the Vector Voltmeter.

> I presume you have undamaged leads for your meter (I won't even
> presume they are calibrated, but for these purposes, testing should

> reveal problems if they are not sufficient to the task).

They are undamamged as best as I can tell. Both channels read the same and agree with a homebrew power meter. I realize the power meter is probably less accurate than the voltmeter.

> I presume your source is powerful enough to present at least 1mV of RF
> to the meter. I know the meter is more sensitive, but you need head

I can use an amateur transceiver with or without attenuators if need be.

> I presume your source is free of spurs and harmonics at that power.
> It hardly is worth the effort to measure out of band products.

The Vector Voltmeter has a 1 kHz bandwidth and a limited-range PLL whose frequency band is manually settable. HP says it will lock to an incoming square wave fundamental without problems. However, I also have the transceiver and an HP signal generator both of which will have fairly clean outputs.

> I presume your source will not pull when presented with a large
> mismatch.

The transceiver will not. I can't testify to the stability of the HP generator at this time. In any case, the voltmeter will track it. My only problem may be that I am unsure of the exact frequency if it gets pulled away from the preset value. I guess I can use the receiver to verify frequency until I gain confidence in the generator's stability.

> I presume your source offers a 50 Ohm output Z. There is nothing like
> a mismatched source looking at a mismatched load to increase confusion
> by the square.

What is the output impedance of an amateur transmitter? I see arguments all the time about this. And even so, what will be the result if it is not matched? If there are reflections from the source, it will show up in the composite forward voltage which will be the reference anyway. Is this not so?

> So, sure, it'll be a snap. ;-)

Richard

I dont know how to thank you. I printed the instructions you give in this thread for me to follow for plotting a pattern from my 137 MH satellite monitoring antenna. I have been overwhelmed with another program thats too dificult for me. But, a few minutes ago I began to try to use EZNEC by following your instructions. Youve presented me with a gift. You have made this 'plotting' fun. I really appreciate what you've done.
I dont know why I didnt start reading this news group long ago.

Thanks

This does not replace testing however. Care should be taken to not
heat the loads as this will cause them to drift in value. Use them
with 1/10 rated power dissipation capacity.

>> Further, you should also swap the dual coupler input/output and the
>> side arm ports to confirm it is in fact operating at fixed ratio (this

>Yes. I did not mention that I would do that, but my plan was to compare the
>forward and reverse coupled outputs and record the ratio of the two.

This goes further than that, reverse the input/output ports as well.
ALL ports must be tested against every other port. Along with the
loads, this becomes an increasingly larger matrix of readings - it is
all necessary. This is about Orthogonality because as a bridge this
cannot be taken for granted.

>I don't
>think the absolute value of coupling (supposedly -30 dB) is needed for now.
>The Narda coupler model is not listed at Narda's Web site, so I'm going by
>the marking on the case.

OK, so it is a Narda. They are typically very good from 10% to 90%
over the band of operation (if you also use the correction factors).

>I have no way of calibrating the Vector Voltmeter.

Such is life. As you are only employing it to make relative
measurements, what you DO need to calibrate is the Gain/Attenuator
range control. Construct or obtain a good step attenuator. This, of

course re-introduces the issue of calibrating it, but if you can reduce variables and check its DC and low AC operation, you are fairly down the road ahead of bonehead problems. If you have fixed attenuators that are of quality, you can do the RF side through substitution.

>> I presume you have undamaged leads for your meter (I won't even

So many mistakenly infer the opposite.

>> I presume your source offers a 50 Ohm output Z. There is nothing like
>> a mismatched source looking at a mismatched load to increase confusion
>> by the square.
>
>What is the output impedance of an amateur transmitter?

50 Ohms at rated output - just like the manufacture specifies. Other useful power settings are not terribly far off (somewhere between 30 and 80 Ohms).

>I see arguments all the time about this.

Nonsense is free of charge, and worth every penny spent.

>And even so, what will be the result if it is not
>matched? If there are reflections from the source, it will show up in the
>composite forward voltage which will be the reference anyway. Is this not
>so?

In SPADES! A source that is 2:1 mismatched feeding a load that is 2:1 mismatched runs the minimum error of your measurement upwards to 20 or 30% [It could be worse, I'm too encumbered to find my reference to quote accurately.] This is why I said your low-ball acceptance of 10-15% error was stardust.

>Is my equation correct and are the comments associated with it correct?

I'm focusing on technique here. I presume you've done your math right. The tougher part is realizing it accurately in a world of error.

>It appears that you have given this some thought. Thank you.

Hi John,

I spent a few years as a Metrologist specializing in RF power measurement. Very, very few know the term (even engineers) - think National Bureau of Standards (or NIST). In practical terms, this

means I have calibrated every item in front of you (and much more).

So, with all the caveats in place, you can easily step right into it by abandoning them all and noting some values. Then you can implement each of these issues and observe how much the data changes. This is the merit of knowing your equipment and your skill. No measurement is right the first time, nor the second, and rarely the third time. Besides, it is more fun to refine your bench and testing and close in on the actual value by hammering out error. The bench artist will even disturb the set up with a known error, and observe how it propagates through to the final determination.

I have used open wire feedlines in six houses so far. I drill two 3/4 inch holes in any wall that is most convenient to bring the line inside and over to the tuner. I ram two pieces of plastic pipe in the holes letting about an inch or so protrude from the wall surfaces inside and outside.

When I move, I yank out the pipe, jamb stucco, wood filler and/or drywall goo in the holes, dad paint on the repair and VOILA! Walls as good as new.

The whole thing is so easy. Why make it hard on yourselves?

1599. Re: PCB costs

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-29 06:41:01 UTC
From: Rick Frazier <rick@rickfrazier.com>
Message-ID: <4090A39C.DB117940@rickfrazier.com>
Source record: 95850

From my days in the Silicon Valley in California, the biggest thing I remember about PCB costs weren't related directly to the size or thickness, they were quantity....

I've had quite a number of double sided PCBs fabricated, along with numerous multilayer ones, and the overriding issue with cost was the "non-recurring costs " of generation of the masks, tooling and setup needed to convert the supplied circuit trace films to finished boards. Once the fixed costs are covered, the individual costs of each board weren't usually all that high, if you had enough volume. As a simple example, a small jumper board of about 2.5" square, double sided 60 mil thick and only about 75 holes, with soldermask cost about a buck each at a quantity of 200. At a quantity of 500, the price was something like sixty cents each... Of course, this was the sort of thing that a hundred pieces would be a near lifetime supply, and at a quantity 100, the price was about 1.75 each.... Such is the problem of amortizing the fixed and setup costs over a relatively small quantity.

So, any price that you get quoted on a per square inch basis will have to carry some serious disclaimers or additional explanation of the fixed and setup costs incurred in making the first board, along with price breaks for quantity....

The best thing to do is to contact some places that do engineering prototype quantity work, and see what they say. You can usually get a decent price quote by providing the outside dimensions, basic construction (thickness, number of layers and copper weight (thickness) along with things like number of holes, how many different sizes of holes involved, whether they are plated through, and whether you want a bare board, solder plating on the exposed copper and such things as solder mask and legend (the exact term for legend, the lettering on one or more sides of the board doesn't come to me at this moment,)) and, of course, the quantity of the run you want made. Of course, tolerance is also important.... If you need ultra-precise registration between layers, that will tend to cost more than an alternate board with a looser tolerance...

It seems like a lot of information, but once you get used to it, it's not so bad.

Of course, if the relative amount of circuitry on opposite sides of the board isn't somewhat equal, (called copper-balancing) the board may have a tendency to warp during manufacture, or even warp or curl with changes in temperature, particularly if one side uses a thick (heavy) copper and the other lighter weight copper. This is especially important if you intend to wave solder the PCB during assembly or other manufacturing processes....

Of course, yet another variable in the cost issue is where the PCB manufacturer is and what sort of volume they deal with. If you're looking for quick turn shops, there are (or at least used to be) a lot of them around the Silicon Valley area. However, if you're expecting to find someone in Podunk WA, KS, OH, FL or similar locations away from high-tech development, you may be looking at higher prices unless they are "hungry".

Good Luck

I'm having a two-way radio. One wide-band antenna was hooked up on a spectrum analyzer. Video BW and RES BW was adjusted to 3khz and 1kHz respectively at spectrum analyzer. Span was 300KHz.

When radio was being keyed up, spurs could be seen at around plus minus 32Khz and 62khz. However, the amplitude were quite low, about -65 to 70dBc. I was wondering what caused the spurs to appear. If radio was connected directly to spectrum analyzer, this problem could not be seen.

When radio was transmitting to different load with different VSWR (up to 8:1), no spurs were seen. Spurs could only be observed while using antenna. Could the VSWR of antenna be worse than 8:1? Just could not figure out the source of the spurs. Please help.

All radios produce these "spurs". The 'source' is in the
design of radio circuits. The service a radio is used in has
requirements as to the level of these 'spurs'. As long as that
requirement is met the 'spurs' are acceptible (not necessarily
desirable, but acceptible).

4003 is very good, but there are many less expensive alternatives, depending on the app and freq required. I am puzzled why you haven't priced this with manufacturer's reps or even board fab houses. They are not shrinking violets, and happy to give you info

Also, it would be helpful to know who you are. Basketball and antennas don't often get placed together.

Your spurs sound very strange, too close in 32 kHz, 62KHz, normally they are
further out several MHz if generated by the RF chain. That is like an audio
part/circuit getting into the transmit RF. Try rearranging or twisting up
the power cables to the radio.
If spurs are low, not much power is there, so little damage to radio
rts. -65dBc sounds good for a CB. The farther you look down the more spurs
there. The antenna could be reradiating RF power back onto circuit
components, which could be a cause too.

Hi Slick

Sure Is!!!!!

I've been self-employed now for about 25 years, trouble is the first 20 of those I only exchanged one predictible boss for about 100 very unpredictable ones, my customers, hi hi.

Then I did away with customers until after the fact. This meant I could basically do it my way, when I wanted to, and when finished then find a customer for it.

I think now I have the best of both worlds. I don't have to deal with customers at all. I have one mfgr. rep. who handles all of the distribution for me. Even had him scheduled to place orders only once per month for awhile, then as he grew I boosted that to ordering only once every other month.

I now run two businesses in similar fashion on alternating months and am working on a third that will be totally out of house, meaning all I will have to do is make a single phone call each time the mfgr. rep. orders or I could have him place the order direct and not bother me at all with it, which is the way I may go with it too.

But it does get boring not having anything to do, so I'm doing hard labor, hi hi. Cleaning out the overgrown woods on a hillside!
Darn chiggers!

It is probably the way you are coupling the spectrum analyzer to the radio. How are you coupling it to the radio when the antenna is on the radio?

If you are just using the antenna on the spectrum analyzer you could be seeing anything.

You may be overloading the analyzer. It is difficult to see down that far and not overload the analyzer with the wanted signal. Try switching in a 10 db attenuater at the front end of the analyzer. Do the spurs drop 10 db? If they drop more you are overloading the analyzer.

You mentioned connecting the radio directly to the analyzer. If the analyzer is an IFR service monitor or another service monitor then all bets are off as to what you are seeing. They are poor spectrum analyzers.

It's been a long time since I've used a VVM. I see 'em in the "send to scrap" piles around here. Richard points out much more than I could and certainly has a more jaundiced eye than I, but this one thing cought my eye

> The HP voltmeter is able to zero out the phase angle between channels A
and
> B. So, I'll put a 50 Ohm dummy load out there for the Load and set the
phase
> angle offset to zero.

I forget how it offsets the phase reading, but I'd start by making the cable lengths so that the two measurement points are "at the same pointy along the line". (of course I have a line stretcher to make it easier)

It sure seems to me that the Zero angle 50 ohm load must be a bad assumption. The 50 could be anywhere angle-wise and is the hardest to measure since the reflected is so small...Wouldn't it be "better" to use a short (of course I'm looking at a couple of Narda shorts at my operating position every night) for a primary 180 degree reference (the open being "harder" to obtain)? I think you mentioned using several other loads as well (parallel 50s=25, etc). I would use several different loads like this to "measure" to see how the measurements look compared to expected (cal-kit style). I'd measure opens, shorts and several other mismatches to make sure all available "knows" looks close, then proceed.
I'd also pad the Tx output. Long lengths of miniature coax in lew of actual power attenuators.
OOPS! gotta re-boot, 73

More thoughts along the lines of John's comments, 32 kHz is about twice the frequency of the horizontal line component of TV video. Do you have any TV transmitters reasonably close by?

I've had problems with detected video on a couple of occasions, getting into audio circuits. After I redesigned the audio circuits to look more like VHF/UHF circuits -- laid out, bypassed, and filtered for VHF/UHF -- the problems disappeared. A working hypothesis is that there's a strong TV transmitter getting into your transmitter via the antenna and/or its transmission line, then getting detected and modulating your transmitter. In the case of my audio problems, the vertical scan component was worse, resulting in a "hum" that varied with the picture of the offending TV station. You might take a close look at the spurs and see if they vary with a local station's picture.

Roy Lewallen, W7EL

My name is Kevin, Mr. Fractenna. The reason I don't call the reps is
because I am not nearly as interested in the numbers they tell me as I
am in the numbers that folks have already negotiated. In this way
when I eventually call them I have an idea of how much I am getting
ripped off. Last time I called a rep he wanted me to pay 60 cents for
a nickel part. So how much I am overpaying is the answer I am after.

You indicate that you are aware of less expensive alternatives to
4003. Would you kindly let me know what those are. Are we talking
materials other than FR408? BTW the frequency is in the 3-4GHz band,
so loss tangent and other stuff only somewhat matters. There is a
price/efficiency tradeoff in play. I would like to 'see the whole
field' before I decide which way to run.

Thanks.
Kevin Smith

The parameters? Admittedly, I did miss seeing them posted until later in the thread. I apologize that you found the phenomenological descriptions to be inciteful rather than insightful. I intended only the latter. It is my sincere hope that whoever it is will soon stop urinating in your soup and/or bunching-up your underpants.

...and that's exactly why you need the reps in.

We do thousands of square feet of PCB a year, and we never had to use a newsgroup to figure out a good price, or ask anyone in the way you suggest. Call the reps. If you want to play games, then you can invite them over on the same day and ask for their best price.

The substrate houses are eager for business and you owe it to good vendor-customer relationships to play it straight. That's my opinion. But hey, what do I know:-)?

BTW, putting FR4 and 4003 in the same sentence indicates you may really need the vendors to fill you in: No one uses FR4 efficiently at those freqs--lousy loss tangent. OTH, I, personally, do not choose 4003 much due to cost, save for very specific high margin needs. But others, of course, may choose these great product according to their needs.

Forgive me for asking this here, but I figure you guys are most like to a) know and b) give a helpful answer.

I stereo receiver needs an FM aerial to be able to receive a better quaoity signal (it's VERY 'hissy' at the moment. What can you suggest? All I want to be able to do is listen to the local FM station that carries the BBC World Service.

If I knew more aboitu the technicalities of this then I'd give you more information, but feel free to ask me more questions, if necessary.

Thanks.

Hi OM,

If you don't have an external antenna, get one (a cheap one seeing you have some reception already, then follow the next bit of advice).

If you have one, get it up higher (add more feedline to accomplish this if necessary). If it is an indoor antenna, get an outdoor antenna (or simply move the antenna outside AND UP).

If you are short on cash (or just don't want to go there), experiment by moving it around and spending as much for 25 feet of extension line. Don't worry about anything except results. If it works fine nailed to the ceiling upstairs - you are finished and enjoy it. Don't worry about connecting wire:
strip the wire, connect, twist tight, and wrap with a some tape.

If none of this offers a satisfactory solution, you will have to spend a little more. Seek a local vendor that sells/installs them and who knows the stations and your need. Radio Shack comes to mind.

1625. Re: End Effect on folded dipoles/monopoles?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-29 20:25:32 UTC
From: richardharrison@webtv.net
Message-ID: <8398-409164BC-269@storefull-3252.bay.webtv.net>
Source record: 95777

Jerry Martes wrote:
"I`d like to get some "real life" data."

End effect on dipoles and monopoles has little do with comparitive performance. See Cebik. It`s more associated with where the antenna is with respect to ground, and how fat or slim the conductors are.

Jerry also wrote:
"I want to understand (see) what kind of pattern I`m getting from an antenna I made for Weather Satellite (137 MHz) reception."

That might be for the NOAA polar orbiters. On page 19-8 of the 19th edition of the ARRL "Antenna Book" is a section on Antennas for Satellite Work. Circular polarization is considered ideal. A couple of NOAA polar orbiting satellites are active and others may be functioning as backups. Active NOAA orbiters may fly high over the horizon a couple of times a day, so you need a program to tell you where, when, and how high above the horizon the flyover will occur. Some are available at no cost, I hear. 15 minutes of visibility, 7 minutes coming and 7 minutes of going may be available on a pass.

On page 19-10 of the "Antenna Book" are shown the patterns of individual dipoles and as used together as an omnidirectional turnstile.

The quadrifilar helix is also considered good as a weather satellite receiving antenna. This antenna is shown on page 292 of J.D. Kraus` third edition of "Antennas for All Applications" in Figure 8-67.

No need for concern about the pattern obtained from folded dipoles if you are OK with the pattern of an ordinary open-circuit dipole. They are exactly the same. The difference is only in the inherent impedance transformation of the folded antenna, dipole or monopole. That`s it. Antenna catalogs list gain as 0 dBd for open-circuit dipole, folded dipole, ground plane, or folded monopole. Patterns shown are the same for open-circuit and folded dipoles. Patterns shown for a folded monopole are identical with those shown for an open-circuit monpole (ground plane).

One catalog lists a thin-wire common dipole as having 34% bandwidth and a 60-ohm feed resistance. The folded dipole has a 45% bandwidth and a 300-ohm feedpoint because it is fatter and folded. The pattern plots are identical.

Enjoy your EZNEC. The resuts it should prduce on ordinary and folded dipoles are already published in many places. Makes it easy to see if you did the EZNEC right.

Best regards, Richard Harrison, KB5WZI

There are front panel adjustments to provide an offset for just this
purpose. There is a selector switch and a variable adjustment which together
provide plus or minus 180 degrees adjustment.

> It sure seems to me that the Zero angle 50 ohm load must be a bad

Channel B (the channel measuring the reflected signal and its angle) is 100
uV full scale at its most sensitive setting. I don't think it is a problem.

> Wouldn't it be "better" to use a
> short (of course I'm looking at a couple of Narda shorts at my operating

I don't know. My assumption is that a purely resistive 50 Ohm load used as a
reference to set the instrument zero is valid. I'm only looking for the
relation of an unknown to the 50 Ohm load.

> I think you mentioned using several other loads as well

I can and probably will do that. Out of curiosity if nothing else. If it all produces expected results, it will increase my confidence that I am going about this correctly.

> I'd also pad the Tx output. Long lengths of miniature coax in lew of
> actual power attenuators.
> OOPS! gotta re-boot, 73

> Steve N, K,9;d, c. i My email has no u's.

I might be inclined to trust an attenuator before the miniature transmission line. The books tell me that the transmission lines can get a little reactive at the higher frequencies because they begin to move from TE1 to another mode. In any case, I think I can adjust my generator to an output sufficiently low so that an attenuator will not be necessary.

Thanks, Steve.

Austin Powers wrote:
"What can you suggest?"

Using a portable FM receiver, find a spot receiving an acceptable signal. Usual problem is an obstructed signal path. An almost line-of-sight path is needed between receiving and transmitting antennas.

Place the antenna for connection to your stereo receiver in the "sweet spot" found with the portable and orient it for best signal to noise ratio.

Best regards, Richard Harrison, KB5WZI

Excellent suggestion. It could save hours and bucks! You might even
get away with an antenna in the attic or upstairs. If you can receive it
on the portable, a simple set of rabbit ears might suffice.

Mr. Fractenna you call it games, everyone else calls it business and
the reps are playing. Are you SURE you are getting the best price for
those thousands of square feet? What if you could knock it down by a
penny/sq in? What better place than a forum like this to figure out
what the right price is?

BTW I know the differences between FR4 and 4003 properties. I don't know the difference in cost so I only have half the equation (if you look above, I told you that there is a cost/efficiency tradoff in place for my application).

BTW You have NOT answered one question I asked so far. It would be helpful if you either answered the questions or stopped wasting my time. You, my friend are the one that's playing games.

I'm having a fine day.
There are too many possibilities to decide with this medium. If you are making these kinds of measurements without an experienced RF Tech or Engineer you will see many many strange things which defy explanation in this forum where many assumptions must be made - and we all will make assumptions based on our experience.

Things to consider:
Location of the antenna - RF could be getting into the radio
- RF could be getting into the Spec Analyzer
Do some radio or antenna moving or even some hand waving to see if a RF field is a contributor.
Get the analyzer as FAR away as possible and if the spurs are gone, forget it and delete the rest of this.

The radio synthesizer SHOULD produce such signals. There are reference frequency spurs. It is rare that you won't see this - however, I realize that your antenna vs. no antenna result is odd and I have no idea what the reference frequency is or frequencies are.
Signal level into the analyzer.
Is the analyzer working properly.
Can you duplicate it?
Can you make any other changes which produces an expected result and get what is expected or does something strange happen. Such as signal level into the analyzer or power out of the radio.
SWR could be an issue as you speculate.
Without being there and trying other "crazy" things I can't speculate further...

Exactly, companies handed out so many stock options that
matured sometime in the future that nobody could afford to
quit the company. That was in the 90's of course when
tech stocks knew no bounds. Don't know how it is working
in the present day.

1634. Receiver dipole vs 23 ft wire for HF

Newsgroup: rec.radio.amateur.antenna
Date: 2004-04-29 22:47:59 UTC
From: Ken <cprstn54zz@att.net>
Message-ID: <e91390dtcl1oh7l5ttrs005t3qc7iv89jg@4ax.com>
Source record: 95783

Shortwave radio manufacturers offer little 23 ft wire antennas on a
reel. See, e.g.:
http://www.universal-radio.com/catalog/sw_ant/3184.html

If I put another 23 ft wire to the radio ground and run it off as
closely s possible to 180 degrees away from the first wire, will this
necessarily (likely?) improve reception?

Excellent suggestion. It could save hours and bucks! You might even
get away with an antenna in the attic or upstairs. If you can receive it
on the portable, a simple set of rabbit ears might suffice.

Personally I have an VHF TV 'rabbit ears' antenna tacked to the wall and
attached. It's approximately the right length for the frequency, and it came
with my TV, which I later gave to my parents when theirs died, who had
cable. (I'm to cheap to shell out for cable and get 1 whole station where
I'm at).

Another method would be go down to wherever you can pickup a spool of 24
gauge wire (like 30-90 feet.. Radio shack sells 90' it for $5), use an
alligator clip to attach it to your existing antenna (or attach it to the
antenna lug if you don't have an existing antenna) and run the wire, say, up
the wall, into the attic, and around the edge of the attic.

1637. Anyone have a 6BTV without radials?

Newsgroup: rec.radio.amateur.antenna

Hustler says the 6BTV will work OK without radials as long as the ground is not dry. The salesman said so also. So I bought it.

I was delayed in installing it because of a nesting Red Shouldered Hawk that I refuse to disturb.

Meanwhile, I am reading articles online that indicate that the 6BTV might work very poorly without radials even with a low VSWR.

I will have a nasty time installing radials where I want to put it.

Anyone have any experience in that regard?

Thanks, Ron

For 1/4 wave verticals like the Hustler, I have had very poor results when ground mounted -- with or without radials.
Placing the vertical on the roof or otherwise elavated -- got much better results with just 3 or 4 radials.

Suggest your read Butternuts blurb on ground radial systems. URL:

The antenna was pointing to any angle and direction randomly while
transmitting. One strange behaviour observed. The spurs could only be
seen at certain angles of transmission only.

Spurs at 32khz and 62khz away from carrier would cause an interference
at adjacent frequencies. A simple test was being carried out. Two
radios. First radio had 502.025MHz as Tx and Rx frequency. While
second radio had 502.057MHz as Tx and Rx frequency. Transmitting at
502.025MHz would cause a interference on second radio, in which we
could hypothesize that spurs at 32kHz away was too high in amplitude
and thus causing interference to other frequency. So, the spurs were
real! It wasn't some kind of 'illusions' produced by spectrum
analyzer. I guess this is highly undesirable.

Besides, I'm sure those spurs weren't produced by radio internal
circuit as I couldn't see any spurs if radios were being transmitted

into spectrum analyzer directly using 50 Ohm coaxial RF cable. Even with 4:1 and 8:1 VSWR load, there's no existence of spurs. Could the antenna's match worse than VSWR 8:1? Perhaps the spurs were part of the intrinsic characteristic of any antennas?

Maybe the culprit was TV transmitter nearby. I have yet to look into that. Another test that can be done is to do transmission in a sealed, interference-free room. If spurs still could be seen, I would say it's the antenna's imperfection that produced the spurs. If spurs gone, it's a good news that the spurs were coming from outer space, Mars maybe.

I would be grateful if somebody could check this out on few radios to see if this problem exists.

Ken, KC2JDY wrote:
"If I put another 23 ft wire to the radio ground and run it off as closely as possible to 180 degrees away from the first wire, will this necessarily (likely?) improve reception?"

Short answer: Not likely.

Regardless of transmitter antenna polarization, received signal reflected by the ionosphere has random polarization. About equal amounts of vertical and horizontal polarization are available for reception. It`s the way the ionosphere works.

It`s advantageous to use horizontal polarization in a receiving antenna for ionospheric signals. It`s because horizontally polarized antennas reject vertically polarized signals and it`s said that most noise is vertically polarized. That`s largely because there is no ground wave propagation of horizontally polarized signals. The ground reflection of a tangential wave has the opposite polarity to the incident wave. The sum of the direct wave and the reflected wave along the surface of the earth is very nearly zero for horizontal polarization.

A vertically polarized incident wave and its reflection are "head to tail" like flashlight batteries and this is obviously constructive rather than destructive. Even so, the earth is lossy at high frequencies.

Received vertically polarized signals come from afar via the ionosphere or via line of sight. Some ground wave propagation exists but it`s very poor. Received horizontally polarized signals come from afar or from very near because the earth treats them so badly. No ground wave exists for them. Excluding vertically polarized signal reception excludes nearly all out of sight signals except those reflected by the ionosphere at shortwave frequencies.

Noise is worse the closer it occurs to the receiver. Noise from a distance is weaker, in general.

Horizontal polarization is a noise suppressor.
A balanced antenna system is a noise suppressor for much the same reason that a balanced transmission line is a noise suppressor. To the extent that noise induces a common-mode signal on both wires, it balances out in the receiver provided the receiver is not unbalanced.

The problem with adding a balance wire to the ground side of the receiver input is that it is likely that the receiver input is already unbalanced. It likely already has a ground return for the antenna circuit, either directly or through a capacitor, to complete the signal

path for an unbalanced antenna input.

A balanced antenna system could be used with the receiver to improve the signal to noise ratio by inserting a balun at the receiver between the balanced horizontally polarized antenna system and the unbalanced input on the receiver.

Best regards, Richard Harrison, KB5WZI

> uV full scale at its most sensitive setting. I don't think it is a problem.

It's not so much a matter of being able to read a value as it is that
the value could be just about anything. Consider if your bridge is
calibrated exactly for 50 ohms, and your calibration resistor is 50.01
ohms...then you get a 180 degree phase angle. But if your resistor is
49.99 ohms, you get a 0 degree angle. And if you put in some little
tiny bit of reactance because of stray inductance and stray
capacitance, the value could easily be at any angle around your
coupler's 50 ohm reference.

But if you put a SHORT at the calibration point (maybe out at the end
of a transmission line), you KNOW it's zero degrees, plus only a tiny
amount to account for stray series inductance.

It's a lot easier to measure an angle at a large distance from a point
than right up next to the point. If you have a thousandth of an inch
measurement tolerance in any direction, you won't have much confidence
in an angle measured half a thousandth from the center point. But if
you are an inch away from the center point, a thousandth of an inch
error is a milliradian, about 0.06 degrees.

It seems to me that it's well worth taking advantage of that phase
measurement capability, because knowing the phase angle of a load, at
the load, will tell you a whole lot more about how to match to it than
just the amplitude info.

FWIW, I've fairly recently experimented with some home-made 50 ohm loads that are pretty good out to 1GHz and beyond. They consist of an SMA jack of the sort that mounts in five holes in a PC board, and 2 100 ohm 0805 SMT 1% resistors. I cut the center pin off so it sticks up only the height of the resistors (or so, not terribly critical), and solder a resistor from the center pin to the shell/ground on either side, so the resistors lie on a single diameter through the center pin. The symmetry makes for quite a nice and inexpensive load. I seriously doubt for anything you will be doing that you'll need any better, out to at least 1GHz.

The SMT attenuators such as DigiKey P11103CT, etc., are a cheap way to get low power attenuators which are reasonably flat up to at least a few hundred MHz. I've been using some similar parts from EMC Technology, http://www.emct.com/, that can handle 2 watts and are pretty flat out to several GHz. But you may have trouble getting them, and they are not so cheap.

Indeed, besides the problems of transmission lines' impdeances changing with frequency, there's a more serious problem for precision work finding lines that are the impedance you want. That is, a "50 ohm" line might well be anywhere between 45 ohms and 55 ohms, and may have small fluctuations in impedance along its length. You can get more accurate lines, but you will pay serious money for new flexible lines guaranteed to be within an ohm or less of 50--and I wouldn't trust a used one! But the nice thing is that you can calibrate out the line effects anyway, for measurements at the end of a piece of line. There's usually not much of an issue about the system being nonlinear, at least. (Certain things we do don't allow the luxury of calibrating at the ends of the lines, so I've become familiar with 1-meter-long lines that cost several hundred dollars. I was shocked at first, but have become numb about that. ;-)

Cheers,
Tom

I agree with the other posters. I had one that worked fairly well
ground mounted, but only with radials for the bands I was using. No
radials for that band meant no performance on that band.

==========

You will have an additional, elevated radial wire.

In some directions and elevation angles and frequencies reception will be very slightly improved. In other directions and elevation angles and frequencies reception will be very slightly worse. On the average, no change.

By changing it to a centre-fed dipole, delete 'very slightly'.

Anyone have any experience or know anything about the Murch UT2000B transmatch. I ended up with one of these in a (retired) lot that I aquired. Says it works 10-160 meters. Power rating 2KW PEP. Takes coax or balanced line. Seems like it is pretty good, it has a rolling inductor.

I was advised to use my 250W Johnson Matchbox rather than the Murch for feeding my balanced line fed loop. I was planning to eventually use a 4 tube 811A type linear amp (like the 30L-1).

Why would someone advise against the Murch in favor of the Johnson for the balanced line?

The Murch has 160M, the Johnson no (unless I were to modify it).

I may have two antenna options, one coax, the other balanced line, maybe I should use both tuners and add switching. (The Murch does not have a built in antenna switch, the switch it has is either "in", "out", Dummy Load, or Grounded.)

Hello Bill,

I used a murch Tuner for many years , it's a fine tuner and will work well for you.. the Reason most people give for using the Johnson over a T- Network like the Murch is that the Johnson is a true Link coupled Balanced line tuner and is a bit more effecent and give better balanced output to the fed line.. I had the murch 2000a which did not include 160M but on 80-- through 10m it workd fine with my horizontal loop and windham antenna.. Use it and enjoy.

Alex,
Will any shortened antenna work as well as a 'full sized'
one? Not really, but it sort of depends on how much it's
'shortened' too.
Would this "shortened" doublet work well as a vertical
'dipole'? Probably as well as any 1/4 wave vertical with
the usual ground system (the 1/4 wave would be slightly
shorter, though).
Is this antenna worth building? I think any antenna is
worth building/trying if you like 'playing' with antennas.
Is it 'as good' as a 'real live' 40 meter dipole? Not really,
but then that depends on your circumstances. If you don't
have the room to put up a 'real live' 40 meter dipole, it'll
probably 'work' very well for you (anything's better than
nothing, right?)...
'Doc

Bill,
I've used both (not on 160 meters, though). For the
other bands, I really couldn't rell any great difference.
If it were my choice, I'd modify the 'Johnson' for 160.
It isn't that difficult, and I just like the 'Johnson'...

I liked my Murch, but eventually got rid of it because I wanted a
built-in switch. I don't know if I had the A or B, but I don't think it
had 160. If I remember right, that was one of the reasons for buying
something else when I could afford it.

I would be careful running power above 20m with it. The losses on 10m
were such that I lost quite a bit of power through it and wouldn't use
it. It was a great beginner tuner in the roller-coil class and I'm
certainly not sorry I owned one.

Also the EH antenna have to follow the laws of nature. The laws of nature is
inthing You can disobey, and get a few Years of prison. It is simply impossible!

So, the EH antenna does not work according the way the inventors claim.
Of course, it radiates. But:

The main radiating element of a "good" EH antenna system is the feeder (koax)
shield. Not the antenna itself.

So, if You have a short feeder, the antenna will radiate very poor (however, it
of
course radiates). And the EH antenna is NOT CHEAP!.

There are some other types og antennas:

1) The Isotron antenna, which is a Q-tank, thus radiates poorly as well,
but the inventors to my knowledge does not make any un-scientifical claims.
You can work some stations with it, it might be a "salvation" if You are
real eager to get on 160, and does not want to do a massive work Yorself.

2) The magloop, an interesting but complex way to make a small antenna.
It WORKS, efficiency is not good, but amazing results can be achieved!

3) DCTL, in fact a magloop, but is NOT recommended for 160.

4) A dipole made of 2 commercially bought mobile whips including coils:
Works, efficiency is not good.

5) A mobile whip.
It is small, and a built in small coil with low Q. Not my kind of tea.

6) Ultra-shortened ground plane aka monopole. A capacitive antenna, which can
be used, if You have good nerves (HIGH VOLTAGE!) and a variometer. Look
what the european 136kHz (LW) hams are achieving! I would recomment this type!
(of COURSE low efficiency, but one can use hi-Q coils, which outperforms
other set-ups)

No type is GOOD for 160m if You have resticted space...

I have a Murch 2000A sitting about 12 inches from this location and
right on top of my AL-80B linear amplifier. I run 1200 watts CW though it.

It is a great tuner! Have used it for over 30 years and I WILL NOT
replace it!

But, it is intended for coax or end fed long wires, not for balanced
lines. I have used it with an old B&W air balun to match 600 ohm open
wire feeders.

==========

Open-ended questions like this are quite in order. Doc, I like your way of responding to them. Valuable when very often when no other replies are offered.

In this particular case a relatively low, vertical, 40 meter doublet, only 12 feet long, would be not much more than one S-unit down on a full size antenna. Just about noticeable. Whereas a high, full-size, 40m vertical dipole would be out of the construction range of the ordinary amateur.

It is amusing to hear about relative antenna gains of 0.1 dB and better in the presence of 10 dB readable flutters and fades.

M3 wrote:
"Any designs for a small antenna to work on 160M ?"

Small antennas are inefficient.

Medium wave broadcast stations have operated from small plots with some satisfaction. They once commonly operated from building tops in the middle of the city.

Building top antenna systems were most often short verticals worked against a ground plane. The broadcaster only wanted vertically polarized radiation, radiated at an extremely low angle.

DXers want low-angle radiation too, but not 0-degree radiation. A horizontal wire must be 1/2-wave high for low-angle radiation; more if conductivity is good under the antenna.

The shortest vertical antenna with a groundplane has a null in its radiation pattern directly overhead but most radiation is at low angles.

The efficiency of a vertical antenna over real earth is bad without an excellent ground system. U.S. medium-wave broadcasters approach 100% efficiency using 1/4-wave towers and 120 radials near the earth`s surface. As antenna efficiency is: radiation resistance divided by the sum of radiation resistance plus loss resistance, the short vertical antenna (whip) has a low radiation resistance and poor efficiency. The efficiency formula has a small numerator, thus a small quotient.

As most mobile operators have found, the short vertical antenna is not the best choice. It is the only choice for an extremely restricted space.

How can the best use be made of a small garden space? Jerry Sevick, W2FMI is pictured adjusting his 6-foot high 40-meter vertical on page 6-24 of my 19th edition of the ARRL Antenna Book. There are several other options in chapter 6 of the "Antenna Book". Get it or a similar book and study applicabilities to your situation.

Antennas scale to most wavelengths.

Best regards, Richard Harrison, KB5WZI

I've had a 5BTV, ground mounted, various types of soil, for over
25 years. On the principle that "anything works," it does "work"
without radials, but not very well, and especially in dry or
sandy soil. The addition of as few as four radials makes a
significant improvement. My radials are buried 2 - 3 inches.

From: David Winfrey <nospam@nospam.ever.net>
Message-ID: <10954i845cjuf32@corp.supernews.com>
Source record: 95815

Does anyone have a working NEC-2 deck for a 2m or 70cm J-pole?
I suspect it'll turn out to involve a dipole, a transmission
line, and an inductive stub all added together, which is
beyond my present level of NEC expertise.

Thanks,
David Winfrey, KB3ICR

Message-ID: <10958j0hohko8ea@corp.supernews.com>
Source record: 95816

I am thinking of buying a beam antenna for HF.
I have been told that some antennas have earthing straps and some dont.

The antenna I have seen is a tribander with traps for 10-15-20. It has no earthing strap on.
If I were to put an earthing strap on to the braid side first to the pole then earth the pole.

Will this A, give me protection against lightning and B, improve signals recieved.
Will there be any other effect. ie: swr etc.

I understand the middle element is a driven element, with an insulator on and there is a director and reflector.

sorry if its a stupid question !!!

Irv Finkleman wrote:
"Excellent suggestion."

Thank you Irv. It`s been tried and it worked.

Someone at headquarters where I worked long ago shipped us (10) new Gates FM brooadcast transmitters, (10) monitor receivers, and a bunch of corner reflector antennas along with rolls of Heliax, and said: Here, use this for STL (Studio to Transmitter Linkage). This was a seasonal hazard. The organization pinched pennys all year to make the budget last, then splurged on anything in sight to exhaust the budget at yearend so that next year`s budget wouldn`t be cut.

We installed the new equipment alongside the old 450 MHz STL equipment (this wasn`t in the U.S.A.). The FM monitor receivers were in the middle of the shortwave broadcast plant, at the time this was arguably the largest plant of its kind in the world.

Harmonics of the shortwave broadcasts were no problem at 450 MHz, but they obliterated our new STL.

So, the FM portable was our salvation. We found a spot several hundred yards from our transmitter building where the FM-band signals could be received with negligible interference from our broadcasts. We built an STL receiver site there and cabled the programs to our transmitter control room. The back sides of our corner reflectors were facing the transmitter building of course.

It's a little ironic that you're trying to save a penny or two on your design and think that bitching about free advice is somehow going to help you achieve that goal...

Look, call up a dozen or so vendors and get some price quotes -- it'll give you some idea of what a 'reasonable' price should be. Figure out what you can charge for your product... if there's enough money left for you to make profit, just go for it and leave the rest of your learning/profit maximization until you actually have an income stream and some track record of the difficulties in building your products.

Anyone worrying about $.01/sq. in. either has such a huge volume that they should be able to afford an expect to get the best prices and redesign the product (this oftens makes a huge difference!) specifically to be easy to manufacture or else is probably never going to get their product out the door in the first place. I've seen many people who seemed to have viable product ideas never get anywhere because they spent far too much time worrying about how to squeeze the last penny out of manufacturing costs and ran out of enthusiasm to simply design and document the product properly.

Dummy wrote:
"One wide-band antenna was hooked up on a spectrum analyzer."

Years ago, from time to time, I`d hear the sheriff`s dispatcher in the background, and sometimes TV Channel 8 audio, when monitoring a certain 2-meter amateur repeater. It stopped when the Sheriff changed frequencies.

Turns out the difference between the sheriff and Channel 8 frequencies matched the IF of my Icom radio. When the repeater opened my squelch, there the other signals were.

In 1949 I used to turn on the Mighty 790 here before 5:00 a.m. when we signed on back then.

From my monitor loudspeaker I could hear KTRH, the 50 KW station about 15 miles away which was already broadcasting. The tiny 740 KHz signal was mixing with the carrier in my final and being rebroadcast. Now both stations are owned by Clear Channel so it would make no difference. It made no difference then either because the 740 KHz signal on the 790 KHz signal was more than 50 dB down. That`s under the FCC requirement at the time.

I think the spectrum analyzer antenna is clean and the "spur" is a simple mixing product.

Best regards, Richard Harrison, KB5WZi

Radials will improve the efficiency the more you have the better the improvement to a certain point of about 120 radials. After that not worth the effort.

> operation. It will work ... but ...

I agree ... I have a 5BTV and it worked well with radials (I only had 2 each, temporary, cut to 1/4 wave at each band, but I pulled them up when I ran the coax in an underground PVC conduit, rather than just laying on the ground and haven't put radials back yet - and it doesn't work worth a damn.)

I intend to mow the grass VERY short and place a significant (64 or so radials of 1/4 wave at 40m) in place with wire "staples" made from coat hanger wire, and then let the grass grow over them (the "staples will keep the radials down until the grass grows over them, eliminating the problem of the mower snagging them).

From my experience, ground mount works well - as long as you have a radial system (more is better, but even a pair per band helps a LOT).

Hi Joe,

So many folks in this group were of incredible help to me in learning about lightning protection, I hope you find similar assistance.

There is no example I am aware of where an antenna of a fixed-land facility can avoid an earth ground and still obtain it's design efficiency _or_ be safely attached to any structure. Grounding is vital to both. From the help and discussions that started here, I prepared a collection of information that turned into a web site for station grounding (one of hundreds out there). But here it is if it will help you, I'm happy.

Thanks to everyone who responded to my post. It looks like the general consensus is to add radials if I want it to work. I suspected that all along but I got talked into it. Dipoles have always worked great for me.

So, now I'm toying with the idea of mounting it on the roof. The back half of the roof has only a 3" pitch, so it's easy to work on. There are lots of trees around to tie the radials to.

I think I will do some experimentation with adding traps in the radial lines. Maybe I can make 6 band radials. Would that work?

I have some time to think about it. The Red Shouldered Hawk's incubation lasts about 33 days and the young fledge in 39-45 days. She's been in the nest for about 14 days so it could be July! Then it might be too damn hot to work on the roof.

Of course, I consider her to be a guest of honor, things like that are major events for some of us :-)

Could be my tiny bit of North American aboriginal blood. My spirit bird is the Peregrine and my spirit name is "Whole in the Night Sky" (Micmac).

I think somebody else mentioned this in passing, but it is worth considering whether RF is getting into the radio via the microphone cable, or whatever the driving source is. You say the spurs change when you rotate the antenna. Do they go away when the radio is at an antenna nul? Can you key the radio with the microphone unplugged? If not, have somebody look at the spectrum analyzer while somebody else is moving the mic cable around.

This might be grasping at straws, but worth copnsidering.

I see you have already put it there. I have the same type of service, but I
can let it download all night, if necessary. I'm off to get it.

Thank you profusely.

John

1681. UHF/VHF

Kind of off topic, but I know someone in here can help me. I have a VHF/UHF TV antenna that is about a year old. I always got great reception with it, but now my VHF reception is horrible while my UHF reception is still good. Anyone have any ideas? I have tried replacing the cable and re-grounded the antenna but the problem remains. It seems to have been getting worse and worse over the last few months.

Thanks,
Dan

Jack thats a great website for lightning protection. There is a lot there I hadnt thought about and it is most useful for me. Joe I have recently bought a secondhand hf antenna which didnt come with grounding straps either, cant answer your question but am listening with interest, because I have wondered that myself.
Its not a stupid question at all only a progression of your knowlege banks!!!
Im sure there are guys who have a lot of experience in this field here in the newsgroup and can tell us all about the benefits of grounding the braid or even if we should.
My antenna is a Cushcraft A3S which sounds similar to yours.

Have you visually inspected the antenna itself for either broken
elements or the phasing line that connects the coax to the antemma
elements. I would start there...

It's not strictly necessary that the radials be resonant on all bands to improve your situation ... I would bet that if you cut the radials to 33' you'll find a noticable improvement. As I said, I had only 2 per band (on the ground) and it worked much better than without any radials. More is better, of course, but in an aerial situation you'll be limited and I'd recommend you try four 33' radials and see how that works.

The idea is to provide an "image plane" for the monopole to "work against" and reduce ground losses ...

Thanks Carl.

I will try that first. 33' should work OK for 40, which is the band I
want most.

Right now the only HF antenna I have working is a 15m dipole. And, 15
has been very quiet here lately.

One of the posters suggested I read Butternut's blurb on radials:
http://www.bencher.com/pdfs/00361ZZV.pdf
I read it last night. It shows a tuned radial using twin lead. It has
a total length of 32' 8". That may be something to try also.

Thanks again . . . 73 . . ., Ron Crowley, W1WBV

Hello all, I found this ad on an old tractor/farm classified ad section.
Size of pipe is not mentioned, but I think this stuff is normally 3" or so.
Could be a great (cheap) deal for a boom for your next HF beam.

Russ KG6TDX

Wes -

I got it. I read it. It did not occur to me that I must short the load to get the phase reference (although it should have). The paper clarifies lots of things for me.

I don't have a line stretcher (I though this was a joke when it was mentioned on this forum). However, it appears I can do without it if I recalibrate the phase offset for each change in frequency. I will probably be mostly interested in single-frequency measurements anyway.

After you mentioned it, I searched the Web for this app note and was unsuccessful. Thanks ever so much for making it available to me.

Shadow

I made a free standing 40 meter vertical out of two pieces of that pipe in
1960. The stuff I used was only 20 ft long, but it was 4 inches diameter as
I remember.

You could fabricate a nice boom with a few 20 foot lengths of that pipe.

No problem, glad you can use it. I have used the technique shown in
figure 11. I happen to have all of that stuff. It is really just a
resistance bridge and could be duplicated for a lot less money. I
have also developed a simple-minded Excel sheet to do the math for the
bridge method. If you're interested,

Source record: 95743

There are two related issues here. One, getting an adequate match between the antenna and the feedline. Two, having an adequate ground plane to achieve the desired radiation pattern. The fact that an antenna is matched, does not of itself mean it will radiate well.

Hi John,

By virtue of Wes' providing you a copy of AN 77-3 and to further offer
you disclosure on the significant contributors of error, consider:
http://metrologyforum.tm.agilent.com/download.shtml

As part of the suite of calculators of error offered there, you will
find the answer to your question above. The "arguments" that you have
so closely observed are fundamentally forced naivete (much too long in
the tooth to be taken seriously). This is simply the consequence of
armchair debate squirming in the face of experience. ;-)

Hi Dan,

Then it is time to look at the other end. There are usually separate paths to the VHF and UHF tuners - although this may have been obsoleted in the years since I've bought a TV. As such, the VHF tuner may have been zapped. There may also be a splitter involved or other pathing issue. Try substituting another TV to confirm it is in fact the antenna system at fault.

Look for a pulled out center conductor in the cable.
You're describing something that's acting like a capacitor in series with
the line, passing higher frequencies better than lower ones.

Also, most antennas like this have a UHF and a VHF section, there may be
some mechanical problem with the VHF section, even if you can't see it from
the ground.

You may not need "the best" best basicly being the *longest* boomed and most elements whigh will have the narrowest angle of reseption and the greatest gain (signal capturing ability) in that one narrow direction, but you need good enough. Better can't hurt (within reason) but no point in spending more than needed or handling a huge far fringe antenna if a more modest one is all that is needed. e.g. on http://www.starkelectronic.com/fmpage.htm the $25 #FM-6 (70" long) might do the job, whereas the cross shaped omnidirectional #FMSS for $19 which is basicly a pair of folded dipoles (like the indoor antenna described above but outdoor mounted and w/o the nulls at the ends) might not. For $55, $75, $200 you get longer (eventually 18 feet long) that will suck in ANYTHING not beyond/below (att least much below) the horizon due to the curve of the earth, IF you have it aimed exactly right.

In any case buy good name brand RG-6 type (as opposed to smaller diameter RG-59 type) 75 ohm coax cable (the signal is attenuated/weakeded faster on small diameter or cheap off brand coax) and if outdoors run a heavy grounding wire from the mast, per electric code in your area (this may mean tied to the same place your electric service is grounded to and may mead adding a driven grounding stake if one doesn't already exist, adn using a grounding block connector on th ecoax line to ground the shield of the coax. If you have an attic you can install it in all the easier/better.

What are you using now? At minimum bet a couple dollar folded dipole at radio shack -- the tee shaped FM indoor antennas made on cheap TV twinlead wire. It will receive from the front and back, but not the ends when stretched straight and horizontal with the leads to the receiver going down (or up). If that's not too bad than a simple 3 or 4 element FM andenna in your attic or on your roof should be enough. It is is poor (or what you are using already) a longer FM antenna w/ more elements may be desired. How far is it as the crow flys to the transmitter, are they a fairly powerful station, and are there hills, mountains, high buildings/a city between you in them (or are you in a valley) etc?

The antenna you need is not really all that differant, electrically or mechanically, than some directional ham radio antennas for the VHF or UHF bands some hams use (say 144-148 MHz, a bit higher than 88-108 MHz).

G'M group,

I recall you could make a fm filter trap using a 300 ohm ribbon cable at some length and put a cap on the end.

I am looking for something like this but would be more for channel 8/9. Or would I be just as well to put a parallel L/C ?

What bandwidth and db rejection would I get with one L/C network? Would need like 10MHz of BW.

de KJ4UO.

>I recall you could make a fm filter trap using a 300 ohm ribbon cable at some
>length and put a cap on the end.
>

An electrical half wavelength with a shorted end or an electrical quarter
wavelength with open end are effective traps. Their bandwidth is rather
narrow.
>What bandwidth and db rejection would I get with one L/C network? Would need
>like 10MHz of BW.

For that type of bandwidth, I would think a single section L/C would not work.
Probably need multiple sections.

Hello,
I need some help in figuring out how to properly use a Spec. Analyzer. I have done several hours of research online now, and have somewhat of an idea of what I am doing, but I just can't get down one piece of the puzzle. In my line of work, we use simple devices that give us the noise floor level in dB. I (stupidly) expected to be able to get this same information easily out of a SA. As you may have guessed by now, I ran into a problem when switching the RBW value. After much... much reading, I fully understand *WHY* it changes (Filters increasing in size cause a greater internal noise level, etc.) but I can't figure the best way to get a "base" noise level reading. And as much as I would like to fully understand the theory, what I really need is a few more examples... IE: If you are looking a 100 MHz span and your RBW is 1MHz simply ___Fill in the Blank____ to find the base noise floor. To further explain what I am trying to do, we are setting up a link that requires a SNR of at least 6dB... I need to get the noise floor level to compare with my projected signal strength for this link.

Please be nice... This is my first post <grin>

Thank you! Thank you!

I am in need of a couple of KLM manuals.
I have searched the net and came up with nothing.
I need the KLM 34A manual the 4 element one.
I also need the KLM 6M5 manual.
a scan is ok as long as I can read the measurements.
These were donated to our club from a silent key last year and now we
want to put them in to service.
Thanks

Getting a decent amount of rejection across one or two TV channels takes a multi-pole filter. You might check out the 5KV series from Microwave Filter Company http://www.microwavefilter.com/multichannotch.htm . They are well made and not too expensive.

RF

Visit http://rfry.org for FM broadcast RF system papers.

Rich -

You may want to contact M2 Antenna Systems
http://www.m2inc.com/index2.html

They are offering upgrade kits (A new set of CNC machined shorting bars, a
new set of capacitor caps
and all new stainless steel hardware) for the KT34A to the M2 version - the
KT34M2
I have to believe the design is almost identical -- except for the parts
upgrades they are offering.

M2 also has a revised version -- the 6M5X (gain 9.4 dBd)

Bill:

N = kTb
Boltzman's constant, temperature in degrees Kelvin, bandwidth.
= -174 dBm for 1 Hz bandwidth

Now, if that short primer does not mean anything to you, then you need to start at the beginning with a couple of good electronics texts, and end up with HP (aggie-lint) App Notes 150 and 243. If you don't get the fundamentals of this down in the beginning, you will never be able to rigorously defend any of your results, many of which will be in error.

It's not clear to me what noise you're trying to measure. If you're trying to measure the thermal noise of a good resistor, you're SOL -- anything you try to measure it with will add its own noise, which you'll end up measuring instead. You can easily calculate the thermal noise, though. If you're trying to measure the internal noise of the spectrum analyzer, the answer is on the screen and, as you've found, it's a function of the filter bandwidth. If you're trying to measure the noise coming from a receiver, it has to be considerably greater than the SA's internal noise, or you'll never see it. That means you'll have to amplify it until you can see it, with an amplifier that's quiet enough that the noise it adds isn't significant. The noise figure of the SA itself is typically much worse than a decent receiver -- it's been traded for dynamic range.

Once you get whatever noise you're trying to measure up to the level you can see it on the SA, you'll find that its magnitude also varies with the SA filter bandwidth, if the noise is broadband. You can get any S/N ratio you want, if you can tolerate an arbitrarily narrow bandwidth. A real receiver has some particular bandwidth to accommodate the incoming signal. It's usually this bandwidth at which the S/N ratio is measured.

1714. Adding lengths to bare wire antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-02 13:43:16 UTC
From: Ken <cprstn54zz@att.net>
Message-ID: <1kt9905f0303bq2vt0fd9fa5e47010d11c@4ax.com>
Source record: 95765

I am making a 40M double extended zepp from bare copper-plated steel wire (26 ga). The wire will be on two reels, each reel holding 87 ft. I will also be able to use this arrangment to make shorter, resonant antennas.

However, the reel is too small to hold 135 ft of wire, which is the next useful length (160M resonant). What is a good way of adding a 48 ft wire tail to the wire on the reel if I find myself on rare occasion wanting to use 135 ft. wires?

I am thinking of crimping and soldering small eyes to the wire ends and joining them with a small stainless nut and bolt. I figure this will take some tension. Is there a better way?

An unrelated question: If it becomes necessary to splice this wire permanently, what is a good way of doing it? Will soldering a twisted 1/2" overlap do the job? How do I keep the solder from tinning (and stiffening) the wire near the joint? Is there a chemical that will repel the solder (anti-flux)? Heat sinks?

Since your wire is so lightweight, only 26 ga., banana plugs/jacks
might work. Otherwise, the stainless nut/bolts should do the trick. It
shouldn't take much -- I've added tails to my dipole with alligator
clips.

Hi Ken,

By the book, such a join would be done with a "Western Union Splice."

This is a join that would be several inches long:

----
the first overlap of wires would be three or so turns loosely twisted
about each other;
----------////-----
-----\\\\----------
each tail would then be tightly twisted in at least three turns around
the wire it parallels.

Hi Bill,

Welcome to the wonderful world of posting.

I'd expect noise levels to be specified in (nano)volts per sqrt(Hz), or (femto)watts per Hertz. This can be experessed in dBm, too, of course. If you know the noise bandwidth of the filter the SA is putting the signal through, then you just take the measured noise floor and adjust it by the ratio of that bandwidth to 1 Hz. So if it were a 10Hz noise bandwidth, the noise per Hz would be 10dB below what you see. If the filter is 100Hz, it would be 20dB below. Now, is the noise bandwidth of the filter the same as the resolution bandwidth? Not necessarily, but it should be fairly close, generally within a few percent. We build FFT-based spectral analysis equipment, and have to document the noise bandwidth of the effective filters, but we also generally have a way to directly display "noise density" which is already in v/rt(Hz) or w/Hz or dBm -- so it's worth looking to see if the analyzer MIGHT have such a function. -- It's worthwhile because of the variation from measurement to measurement to use as much averaging as is convenient. This might be called "video filtering", but is done after the signal filtering and detection. Lessee...what else. Normally, the base level noise of the analyzer would be measured with the input terminated in its input resistance, usually 50 ohms.

Footnoote about the bandwidths: the noise bandwidth (or noise power bandwidth) says if you have an input signal of, say, 1.000 picowatts per Hz, and it's uniform power density per unit bandwidth (a flat, broadband noise), and you measure 12.345 picowatts coming through your filter, then the noise bandwidth is 12.345Hz. That may differ from the -3dB bandwidth of the filter, though generally not by a huge amount. With analog filters, it's probably expecting a lot for it to be really the same from analyzer to analyzer of the same model, but with digital filters (not necessarily even FFT-based), it should be spot-on the same from one to the next.

Cheers,
Tom

What is the "Bandwidth" of the "stuff" you are trying to measure?
You could set the analyzer to that or a little less, and then use relative measurements.
You may need more gear if you are trying to measure a very low noise wideband preamp.
Depends on what you are trying to measure.
Bigger bandwidth=higher noise floor, simply kTB. and it is a ratio if you change kTB1/kTB2= B1/B2 (10 log it of course)

If you have the analyzer on, then connect the gizmo without signal and the noise floor rises up 10 dB or more, you could probably ignore calculating what the SA contributes. just add signal and it should be 6 dB or more above noise floor established by your gizmo.

If not, then It is possible to calculate almost exactly the noise floor on the analyzer to verify what is displayed is good, but you need a number or two from the MFGR of the analyzer, which takes into account the filter shape of the analyzer. (0.8 ot 1.6 something like that)

SAs are cool! What type do you have, makes a big difference, (depending on what you are trying to measure) Some will not do it.

Ken,
Your idea with the nut/bolt should work, or, just solder
the 'tail' on. Any soldered joint is going to be a bit
'stiffer' than the rest of the antenna, so keeping the joint
as short as possible would probably be less 'stiff' than a
longer one (not really, but easier to manage, maybe).
If you had another couple of reels, put the 160 meter tails
on them and use the reel(s) to 'chunk' over a tree limb. Make
the connections with the 'free' ends of the tails...
'Doc

Ah, good point! I was fixated on the antenna end when I offered up
advice to Dan. Being that it has been getting worse GRADUALLY, you have
a very good point...may be in the TV tuner itself. Hate when THAT happens!

Do you mean television channels 8 and 9?

I'm kind of guessing at what you're wanting to do, but the easiest
trap is the 1/4 wave open stub. If you're trying to kill off
TV signals, tune it to the video carrier frequency. The length of
the stub will be a physical 1/4 wave times the velocity factor
of the cable you're using (close to 1 for twin lead). Start
long, and trim off just a bit at a time till you get it right.
(That's hard to do, because you don't really know you've got it
right until you trim it off too short and realize you've gone
past your desired notch frequency). Better is to cut it a bit
short and put a trimmer capacitor across the end of the stub,
then adjust the cap for maximum attenuation.

The notch will be very sharp, so you'll need seperate traps for
each channel.

Thank you so much for all your help (Crazy George, Roy, Tom, John)!! Per Crazy George's suggestion, I am picking up some books tomorrow at Borders <grin>. However, the posts that I received were very helpful. Let me explain a little more what I am trying to do, just to see if I am even close to the right track. We have a Microwave link that operates at 5 GHz... specifically one sides transmits between 5.25-5.25GHz and receives at 5.725-5.825 GHz. The product we are using for this link is a Stratum 100 (http://www.commputercations.com/products/wsstratum.htm - The only datasheet I could find). This link went down hard a few days ago, so we switched polarization (From Horizontal to Vertical). Things got much better, but we still were taking corrupt packets. So, we went out there with an Advantest R3465 SA (http://www.ntecusa.com/graphics/pdf/WE106.pdf), an Omni antenna, and 10 degree directional dish, with the hopes to (1) look at the "same" noise floor that the Stratum sees and (2), try to track down any single direction (And hopefully antenna) that is causing interference. Now, I thought I knew this stuff <grin>, at least enough to retrieve somewhat accurate results. Boy was I wrong! I scanned the receiving frequencies using the following settings:

Start Freq: 5.725GHz
End Freq: 5.825GHz
Span: 100MHz
RBW: 5 MHz
VBW: 1 MHz
Sweep Time: 50ms
ATT: 10dB
REF: 0.0dBm (10dB/)

Knowing what I know now, I would have kept the RBW value MUCH lower (Like 10kHz). But what I saw was a "noise floor" - Which I was assuming to be (I believe) the Thermal noise floor which I now know to be the Filter Noise Floor, peaking out at about -64dBm. Now our receive strength when the radio is on is -65dB... So I figured "Hey, there is our problem... the receiver in the Stratum unit is seeing the noise floor so loud that it can hardly see the actual signal". What makes this even more believable is that these readings were taken in the middle of Boston on the 26th floor roof. So I packed up and went home... Then I tried the same test at my fairly isolated house... and got the same results!

Now I know there is at least one answer to how to avoid this embarrassing situation in the future... read a book (Which I will start tomorrow)... however, I really would like to get this link up in short order and need to know these numbers. Am I correct in saying that I need to (1) contact the manufacture of the Stratum unit, and find out what their Bandwidth filter

looks like and then (2), Set my RBW to the same or lower setting as their radio and do the test again?

If the above two steps are correct than great... I can do that... but I really would like to make use of the measurements I already took if possible.

Again, I really appreciate the comments from before. While I don't yet understand all of it, these really point me in the right direction, and I will keep reading/researching until it all comes together.

Thank you,
Bill B. - N1SNI

I assume these unit are the unlicensed variety and use spread spectrum technology (frequency hopping)? If interference is the cause, it may be hard to find since you probably don't know the discreet frequencies used in the hops. If I am understanding you correctly, you are looking for the ambient level of noise coming down your coax to the radio? I know just enough to be dangerous as far as spectrum analyzers go. We just plug the coax into the analyzer and see where the "fuzz" is located at the bottom of the display, i.e. -108 dbm.

I am not familiar with the radio you are using, but if it like the ones we use, can you swap frequency bands such as Band A or Band B? We have some Lynx and Tsunami 2.4 GHz T1 radios where the back filter unit comes off and we invert it to select another band of frequencies. Might be worth a shot if you can do it (to both ends of course!)...

Good luck! Let us all know what you find!!

That`s pretty small.

If you don`t Nicopress, the "Western Union Splice" is a good alternative. It is shown on page 20-4 of the 19th edition of the ARRL Antenna Book as Fig 3. A copper-wire Table on page 20-2 relates wire size in AWG / B&S to English and Metric sizes and other characteristics.

Much good information is in the 19th edition of the ARRL Antenna Book, Chapter 20, for those who would hang wires, rods, or tubing in the air.

Your Software Must be robust enough to accept, reject and process corrupt packets as you will Always get them with wireless, always. --You will ALWAYS have bad/corrupted packets with any wireless system.-- The 5 band antennas have very splintered patterns, and ducting from point to point. and you will have +20dB one second and -20 the next second, your firmware, and software must handle this stuff, RF cannot do it alone. Mother nature set the rules on this one.

The MFGR will tell you the max range, and the dishes to use, rain degrades the signal, as well as heat (ducting) The big boys use 4 dishes for a link ATT @ 11 Gigs two on each side spaced vertically some so when ducting occures, the other dish picks it up. If the cost is low enough, you could put in another entire link as backup. Also % of packets getting though is an indicator of SNR, but that can depend on how you have the link hooked up, as a LAN extention, you have timing constraints, and so on. 90% or better is great. Less than 20% you may have a link or LAN timing problem (path too long, pointing is off, ducting, SW lame).

On a roof in Boston, your 5 gig unit may be susceptible to radio and TV interference, the scan may be detected on a junction in the unit. Signal blasts through the case and so on. Urban RF is a dirty world, and we can't see it either!

Assuming classical "noise" as we are all probably thinking...
First, a minor correction to the above "considerably greater", Roy. If the EXternal noise is just 6dB above the SA's INternal noise (I guess 4 times can be considered 'considerable'), then the resulting displayed value will be only 1 dB higher than the incomming noise actually is. Noise power (when combining in one receiver) simply adds. To see the math, think this way. A 1 dB increase amounts to 1.25 times the power. That extra 25 percent is one fourth the original power. 25% of the power is 6dB down from the original. SO adding some power which is -6 dB (or 25% the original) will raise the total 1 dB.

However, The poster used the term "noise", but doesn't know the source of his problem. His data hits can be caused by other than what we are thinking is noise. It can be (sounds like since it recently started) spurious signals in his channel OR it could be IM being caused from strong signals getting into his receiver. The spurious in-band stuff could be narrow signals or wideband. Typical CDMA signals behave much like simple wide-band noise as we think of noise. A narrow band signal/spur is different.

From a later post I see that he is trying to measure some junk that has appeared on the link frequency causing interference. In any case, the front-end noise floor (noise figure) of the SA will determine how far down you will be able to see and if it is not low enough, then you won't see the interference. I can not comment on the Advantest sensitivity. If you have access to a low noise amplifier of the type used in your system, it can be used in front of the SA and *MAY* raise the sensitivity (lower the noise figure/floor) enough to see yout interference.

Good luck. We've had a strange low level (around -123 dBm)spur on our repeater input since last fall and can't locate it...wish I had lotsa time.

Finally a thoughtful response. BTW I have called up the vendors,
that's just common sense, but the prices they quote are rediculous
even if you promise them volume. They don't believe you about the
volume (rightfully so, that's why I am asking someone who has the
volume) and at those prices there is no business. I have done all
that analysis.

Yes, I am worried about $.01/sq in. That's a buck on a 100 sq in
board. That's A LOT of money to me. BTW, I have done as much antenna
footprint minimization as possible (that's a different topic). Now to
your point about never getting anywhere due to too much time squeezing
out pennies. I have experienced a lot more of the opposite, where
people build stuff without paying enough attention to the costs and
then figure out that its too expensive and try to cost reduce. At
that point their previous decisions limit their options and the stuff
can never be built cheap enough. So I am trying to strike a balance.
And if I can get a quick answer on what those costs are, that would
leave me more time to optimize the design. BTW I am NOT asking who
you are, I am just asking how much you pay. That's the beauty of
these boards. I don't see the foul.

ps Free advice is the goal of these boards, I am not bitching about
the advice, I am bitching about lack thereof.

I gotta think you must be taking the wrong approach with these PC houses if you can't get an answer from them. Besides, the answers you get from us don't amount to much if you can't get anybody to make your boards for the prices "quoted" here.
Bottom line is you won't get the low digit price unless you're going to spend some big money. If you let the PC houses know how big a project you have, and it's big, then they'll be plenty anxious to quote you a good price.

I am now in the market for a new vertical after my old R7000 was hit by lightning.

My old R7000 was mounted on a 45 foot Tower. (At this height, the antenna worked great!)

I am considering purchasing a SmallIR vertical (from www.steppir.com) and mounting it on this 45 foot tower with radials dropping downward from the tower. I won't be able to easily guy the vertical but it would appear that it is pretty strong with a 80 MPH wind survival rating without radials.

Is it a good idea to install the SmallIR on top of a 45 foot Tower?
Has anyone successfully used the SmallIR vertical mounted on a 45 foot Tower?

I am also considering purchasing the BigIR vertical. But if its guying requirements, I won't be able to mount it on the Tower. Instead, I am thinking of using my elevated deck as a support. My Back wooden deck is about 9 foot off the ground with a 4 foot fence and some posts about 7 feet tall. I am thinking of mounting the antenna feed point about 8 to 9 feet off the ground and use the bottom of the deck to install radials. I will use the post to provide additional support instead of using guy wires.

Will this work? (I realise I will have to fiddle with the length of the radials)

> various solid state and tube conversions.
>
> Thanks in advance for any help.
>
> WA3MOJ

First, the circuit techniques for UHF receiver front ends and
transmitter PA's are totally different than those on 11 meters.
Conversion becomes wholesale replacement of about half of the radio.

Second, <<`ALL'>> CB radios must be type-accepted by the FCC for use
on the air. Unless you have the thousands of dollars for R&D, and
legal assistance to complete this, forget the whole thing.

What you are trying to do is tantamount to modifing a VCR into a
satellite uplink to jam television satellites. Can't get there from
here, No how, now way. Zip. Nada. The BIG goose egg.

Now you could use UHF commercial radios on the GMRS (former Class A CB
channels) with very little problem. Just change crystals or reprogram
the synthesizer in the radio, tweak, and you're in business. Any
competent two-way radio shop can do that.

I'd suggest you study a LOT more on basic electronic theory, and
circuit design before you post such an asinine question.

Rob, You must enjoy spending money on antennas:-) If you can get an inverted vee up 45' at apex, and feed it with ladder line and a tuner, then you have something that will exceed what you are proposing. A 50-65' per leg vee will get you on 80M-10M, and possibly 160M.

The performance on the lower bands (160M-40M) will exceed any store bought vertical. On 20M-10M you may not see any difference in performance, depends on what dx you are trying to snag.

If you are going to put a vertical 45' in the air with radials sloping downward, why not try ladder line and a tuner and see what happens. You will spend considerably less $.

At the present time, I use an indoor "powered" antenna. Almost all of the stations in the local area, (3, 12,16, 27, 29, 35, 40), come in clear. Channel 3 and 12 are usual "fuzzy", but normally watchable. Channel 27 can be difficult at times, but 35 is the worse. There are times when the picture is unviewable, and it is never really clear. The tower for Channel 35 is appr. 30 miles away, all of the others are less than 10.5 miles. The ground if flat, with a few good size oak trees in the area. I have a 25 foot tower which I removed an old non-working antenna from.

My thoughts are to buy an external antenna and try it out, buy a pre-amp only if needed. By the way, I plan to split the signal with the longest run being about 80 feet from the top of the tower. My only concern is the length of the longest cable, which happens to be to the main TV which we watch. If channel 3 and 12 didn't give me problems, I would just buy a UHF only antenna. I am looking at the following antennas: 3010 or 3016. The non-amp 3016 appears to give better numbers, according to Channel Master's website. Does any one have either one of these, with and without a pre-amp? Will the 3010 with an amp,(CM3038), give me much better reception then the 3016 without? (I have a chance to buy one from another individual). I don't care about the fancy numbers, I just want to know, will both of them give me the clear pictures I'm looking for?

Thanks for your suggestions,

John

Hi Rob -

You might talk to the SteppIR folks about using one of their DIPOLES on your tower. It could probably be mounted vertically if you were so inclined.

If I were going to try that, I would try it first without a balun, and make sure
the dipole leg adjacent to the tower was connected to the shield side.
But you could be assured that the dipole would work killer in the conventional
horizontal orientation, IF the airspace it occupies isn't a problem for you.

Have fun es 73, Ed

Source record: 95693

Hi Ed,

Thanks for the post. Well I considered the SteppIR dipole instead of the vertical. But my Tower is a self supporting TV Tower. It isn't that strong. It handled the R7000 without any problems. But I fear that extra windload of a dipole (or my dream yagi!) would be too much. (One day I will put up a real tower and a yagi!)

I like the low DX angle and omni directional pattern of a vertical. I live in the country so QRN is not a big problem.

I have found that the R7000 vertical worked much better up 45 feet than mounted 8 feet from the ground (as recommended by Cushcraft).

I would like to avoid traps and go with a STeppIR vertical. But only the small StepppIR vertical can be mounted practically on a Tower.

If I want 40m and 30 m coverage, I need the BigIR and mount it near the ground. (Possibly using my elevated deck as support and using the bottom of the deck to support the radials).

Decisions.. Decisions.

Rob

1743. Telescoping Masts

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-04 00:55:48 UTC
From: zeno <zeno@sonic.net>
Message-ID: <4096EA13.B2B05674@sonic.net>
Source record: 95692

How the heck did those TV crews of yesteryear erect 40+ foot telescoping antenna masts sitting atop pointed roofs? Its not exactly like you can set up a step ladder on such a roof to get up the first 10 foot to pull up the rest of the sections. Also setting the guys correctly is nothing to sneeze at I am finding out. Maybe they worked it from the top section down...of course.....! Pluse they already knew from previous experience with standard hardware how long to make the guys....I beginning to see the light....not that I can use that technique.

At the moment I am still recovering from the stress of a yet unfinished mast erecting project and when I calm down or when I am out of deep water so to speak, I will tell you the rest of the story of untangling the pre-strung guys and ropes etc. It is one of those crazy situations where you yourself are the only accountable engineer, everyone thinks your crazy, and you dare not tell anyone what you were thinking because they would just tell you that you must be nuts.

Mostly I better keep this project to myself until I am either out of the hot water or I abort it. Please wish me luck since I am a fellow antenna dream farmer gone of the deep end it seeems.......

BTW, I am not trying to do this atop such a pointed roof, and it still is quite challenging. One is almost up leaning on on end of a barn, another will be free standing out in the field, another will be tied onto a 20 foot "telephone pole" set in another part of the field (hoping to get an additional 24' or so. Plus two more I won's even go into..

then, I heard that sky wire loops are nothing all that great anyway......

talk about taking the wind out of one's sails when one is in the middle of an engineering crises....its all the fun of AMATEUR radio......amateur with its root meaning "to love"....

I suspect you can get near the same performance with an inverted vee. But the vertical will likely have a better DX angle and will be a little more omnidirectional. Also it will be faster to switch bands with an R8 or SteppIR. No need to fiddle with a tuner.

Well I have insurance. The Insurance company will pay for the new antenna and installation. But I need to supply them with an invoice showing the purchase of a new antenna. (It doesn't need to be a vertical but the insurance will only pay for the equivalent replacement cost of a R7000 vertical. I could go for a more expensive yagi but a I would also need to buy a real Tower).

That is amazing, like you say.

Now that you mention it, I see no other way to do it. So I guess I will quit my bellyaching about doing just that out in an open field pulling up 4 ten foot sections after the first base 10 feet is mounted and guyed.

How did you secure a step ladder on the peak of a roof?

Hi John,

For a 50' tall mast, what would you say would be the minimum acceptible square dimensions from vertices (on a flat plane with the base) of the guy wire anchor points?

Since it is easy to design a 100' mast with no guying required, there is obviously more information required to answer that question.

Folks we are missing the point here. I can certainly get a quote from them. You can safely assume I already have it. Ok, that tells me the MOST I am going to pay. Now I want the LEAST I can possibly pay. The only way for me to get that is to go through board manufacturers' cost structure and assume their take. I am not TI or HP, I don't have the resources to do that, and even if I did I wouldn't get it right. Now why would I want to know the LEAST even though I can't get that price at this point. Well, the situation is likely that if I have to pay the MOST, I lose money. Do I still lose money when I get to pay the LEAST? (As far as getting the houses to quote a big project) I can't get the big project funded, much less quoted until I understand that.

Look people. Determining the 'right' price is one of the 'killer aps' of the internet. Use it.

Well, I guess I will just put the guy wires as far out as I can without bumping into the trees in the orchard.....or I might just not put up this extra 50' mast at all, but that means I will have to span nearly 180 feet on one side of my square loop skywire.

I am already falling out of favor with those around me here with this crazy antenna project....such is the misunderstood life of the ham ....at least I am in the country and it is my own place....and the waf is not an issue at the moment. Some people do not find a 50 foot mast in the middle of an orchard as beautiful as I do. I think the "industrial" aesthetic needs to be boosted a bit these days....fortuitious pun...perhaps intended....

It will work, but I'd rather have an antenna on the tower at 45 ft any
day. I think if I had to choose between a smaller antenna higher, or a
longer one lower, I'd usually prefer the higher smaller antenna. But
of course will depend on the number of radials you have at the lower
level. I don't know what bands you prefer, but take 40m...At 8-9 ft,
you would probably need at least 60 radials to equal the level of
performance of just 4 radials at 45 ft. MK

I'm planning a couple 50' telescoping masts with pulleys at the top to hold up a long, center fed Zepp. I plan to erect some scaffolding around the masts so the deck is at 8-9 feet, then pull up each section while using temporary guys until it's all the way up, set the guys, take down the scaffolding, hoist up the Zepp and have a beer.

I haven't done it yet but it would seem that it would be easier standing on a deck, not balancing on the top of a ladder while lifting so much weight. Scaffolding gives you a bigger place to stand, big enough you can add a second person and make it that much easier. It also serves to help hold the mast vertical if you tie the bottom section to the scaff.

I could see setting scaffolding over the peak of a roof to set up a mast there.

Bill:

You need to enlist a little geometry and mechanical engineering. We like to keep our top guys at 45 degrees or less (ground up to guy) where space permits. The down force on the mast for each guy is then .707 of the guy tension. As the guys get steeper, the down force on the mast becomes a larger and larger portion of the total tension. So for a smaller 'footprint' with the guys near straight up, any side force on the guy from wind or antenna tension becomes a larger down force on the mast. I need to make drawings to clarify that point, so find someone mechanically inclined to wave their hands and draw lines and make calculations for you.

As far as the stepladder on the roof, consider the average male is just under 6' tall, with an 18" up reach. So he has to stand only 4 feet above the mounting level of the base of the mast to erect it. A 5 foot stepladder straddling the peak of most roofs is relatively stable if you are young, limber and agile. Having the first (bottom) section SOLIDLY guyed is a must. At least that's what I remember from the middle of the last century.

John Smith wrote:
"The big boys use 4 dishes for a link."

Yes. It is for space diversity which dramatically improves reliability on many paths. Paths tend to fade independently when they are significantly separated, say by 10 wavelengths.
More than just 2 antennas at a path end is required for diversity reception. Separate receivers are required too.

Two dishes connected together just make an antenna array. If both receive the same signal, it is probable a time will come when the signal sum is zero even though either signal is usable.

Two receivers or more must be used for space diversity reception. A special combiner must be used to select the best signal and reject all others. Individual receivers are connected with individual antennas and selection is made from among the receiver outputs. All other receiver outputs are completely rejected.

The shortwave broadcaster I worked for in the 1950`s relayed its programs via HF radio. There were 3 rhombic receiving antennas, separated by about 10 wavelengths broadside, at the lowest frequency. This was repeated for each reception direction. Each rhombic fed its own multicoupler in the receiving station. A receiver for each frequency being received was connected with an output from a multicoupler.The receivers were all Hammarlund SP-600`s.

Three receiver outputs, representing signals from each of three antennas were fed to a "triple diversity combiner" (Crosby or Pioneer). The combiner selscted the best of the three signals and rejected all others. This is a triple diversity reception, "TDR System".

In the 1960`s, I built a diversity microwave system into the Gulf of Mexico from onshore. Water can often reflect well enough for complete signal cancellation at microwave frequencies, so I used space diversity, two dishes vertically separated on the towers, feeding separate receivers at each path end. Only one transmitter at each end of a path operates at a time., but both receivers work with a combiner which functions like that used at HF for the TDR. Output is a video type spectrum rather than audio output as from the TDR combiner. The video combiner picks the better of the two received demodiulated microwave signals and rejects the poorer signal. It works like Gangbusters.

Best regards, Richard Harrison, KB5WZI

Hi Bill

After a serious fall a number of years ago, I am now terrified of heights like you wouldn't believe.

Yet I am still able to put up 50 foot towers, push-ups and even sectional guyed poles by myself with no problems.

On push-up poles, I lay them on the ground first, open them up, make point to point guy ring measurements, mark the poles for their maximum safe expansion and close the assembly back up and haul it up to the roof.

The main body is guyed and finished off prior to doing anything else. Using the formula to find the hypoteneuse the guys are marked for full length, then remarked for each lifting stage of the operation.

The antenna or antennas are affixed to the innermost or highest part of the mast, which is only extended at this time long enough to do this operation. The ladder to reach them is set on the roof and tied to the now rigid base mast section.

Before lifting, the guys for section one are clamped at their first set of markings, which allows a little slack or you couldn't lift it to the proper fixed height. After the clamps are in place, as you lift the first section, the guys slide through the eyes until they near the clamp. The mast is only lifted about 2 feet at a time and the standoffs for the ladder line are installed or the coax affixed to the mast with ties. Again it is lifted another 2 feet and a standoff or tie or both are installed. Repeated until you reach your 10 foot marking and this top section is then locked down solid.

Now clamps are installed to the guys for section two to the first marking, the clamps for section one are loosened and clamps installed on the second marking for the upper guys.
Here is where it helps to have 3 or 4 extra helpers to feed guys and keep them fairly taught. But if you don't have them, the pole is not going to fall further than the next set of clamps on the guys, or about a 2 to 3 foot lean at this early stage, the lean gets less as the guys get longer.

The second mast is pushed up, usually by bouncing it so the first clamps of the section one guys can slide on the cables but still have enough tension to hold the antenna upright for you.
Again, working in 2 foot increments, the standoffs and/or ties are installed.

By the time you get section two up to maximum height, you will not be able to lift the remaining sections by hand. It's not the weight, it's the tension on the guys and floating clamps that are your enemy. If your familiar with how a Pony clamp set works, I had a similar tool made for lifting push-pole sections. A clamp is affixed to pole two and to the main mast in two places. I simply turn the handle to lift the pole about 8 inches, then lock it down, crank the tool back down, let it catch the pole and unlock the mast and crank it up another 8 inches and repeat until I get to the two foot point. Then I install the standoffs and/or ties or both. Then repeat again.

Once the whole assembly is at full height, the guys are then tensioned to their proper rating. If your guys are NOT equal distance from the tower, you will have to make adjustments to the tension settings to maintain a perfectly vertical pole.

Many of your guys themselves can be used as antennas if you plan for this before setting up the system.

I put up an 80 foot vertical single handedly using only 1 inch 10 foot sections of interconnecting pipes. We had intended going up 100 feet, but the pipe was not strong enough to hold itself without telescoping and splitting, so we halted at 80 feet. It stood for 9 years untouched and without problems. Taking it down was really simple. One hit to the lower pipe with a baseball bat and the whole thing came straight down on itself and finally stopped dropping at about 15 feet of height and leaned over, the antenna did not touch the ground and was salvagable.

I installed a Hy-Gain TH-3 Jr and an Alliance TV rotor on a 20 foot TV mast on a 2 story house -- used a heavy duty antenna tripod for a base-- total height 42 feet.

The drill was with 5 "Amateurs":
1. Under the roof -- installed 4 by 4's to take lag bolts from the Tripod base
2. Bolted down the tripod mount to roof and 4x4's -- under the roof added sealant to prevent water entering.
3. Raised collapsed TV mast with antenna rotor and 4 guy wires --secured in tripod
4. Guyed the 10 foot section with the 4 guy wires
5. Set step ladder next to 10 foot guyed section -- secured ladder with rope to mast
6. Stong buddy also held ladder against mast
7. Tall guy (me) ascends ladder. Had rope around my waist in case I nose dived off of the ladder
8. Horsed the collapsed section with 4 more guy wires attached -- up to 20 feet - secured guy wires (Total 8 guy wires)
9. Fed all hands Pizza and beer.
10. Antenna stayed up there thru storms winds et al for 15 years before I moved.

Your installation may vary -- this is just the way we did it -- but we were are not professional installers, so caveat installer. I take no responsibility for your installation.

You should contact professional TV antenna installers for their approval -- or better yet -- let them install it.

Hi George,

A 45 degree angled guy from the top of a 50' tall mast will be out 50' from the base of the mast. That would suggest that the "square" made from the four anchor points is 100' on a side. I will have to look at the site and see if that is possible.

Bill

Hi Gary,

Thanks for the thorough instructions. I am not sure I understand the pony clamp, but I agree that I can see a problem trying to lift up the combined weight of the last 4 of the 5 sections after the first 10 foot section is in place. Where can I see an image of such a "pony clamp"? I have two people trying to pull it up maybe it can be done by hand.

I think what you need is a book on the business of manufacturing. The price is basically going to fit a line y = mx + b. Think of b as a tooling charge. The unit cost is m. x is the number of units, and y is what you pay per lot.

Only three guys are needed. Your 100 foot number may be in error.

How about 75 feet between anchors in a three guy wire system?

I have seen what appear to be AM broadcast towers in or on the edges of salt marshes, and it seems pretty obvious to me why that's a good place to go. However, the environmentalists being a little more noticeable than they were once upon a time, this particular method of siting is probably a little more challenging than it used to be.

I recognize that salt water is far more conductive than fresh water, but fresh water's still superior to sand and the like. That being said, I am wondering about using a pond as a ground screen and mounting the antenna itself on an island (or a raft) in the middle of the pond.

What I don't know is just how large a pond do I need in order for something like this to work? Obviously it depends on type of antenna and band and a bunch of other things, but even a wild-ass guess (with some math or physics behind it) will help make the difference between whether I bother trying or not.

For those who absolutely require less variables in their equations, imagine a standard dipole tuned for 20m strung roughly 45 feet above ground level between two trees, one on either side of a fresh water pond. How wide does the pond have to be at that point (and others) for it to work right? Even answers like "the pond will have to be wider than the dipole is long" or "there will be no noticeable impact on performance" are fine if they're based in reality, and ideally in math and physics I can understand.

Oh, and another question: what difference, if any, would frozen versus liquid water make in this situation?

Jack.

Please Kevin,

Don't be so righteous. I told you what to do on a private e-mail, way before you sent this. If you couldn't get pricing from the reps--REAL pricing--then I would provide it.

I, too, have priced out boards for microwave apps, and I certainly didn't need to go around the reps.

We need to keep a viable substrate industry continuing in this country, and anything that could be construed as undermining them is not in my vocabulary. They've bled way too much already.

> of the internet. Use it.

I think the price is going to be fairly constant within a certain volume, unless you can find someone that does it on the side for a lower price. I used to work at a circuit board company about 20-25 years ago. "Chemetch". I don't think anyone really got any special deals, unless the order was ready to be placed, and the volume required was pretty much known. You just gotta dicker with the sales person. That company was quite high priced actually. Maybe the highest in town, but I didn't do sales. But the quality and inspection was top notch. Thats how they justified the high price. But, the owner knew a few people that did small volume board work on the side, and he let them "rent" his facilities to make boards at night before normal work hours. It's one of those types you want to talk to , as they are always looking for work on the side. We made boards for loads of big companies, and also NASA. The NASA guys were *real* picky about their boards, and thats why we got most of their work. But they probably paid through the nose... They used to have guys in MIB suits/white shirts come around to inspect the boards during the construction stages. We also made boards for loads of other companies, including TI, medical co's, oil , etc. I use to make HUGE double side boards for medical gear. But also little round boards for digital watches and the like on the other end...I used to have to inspect so many of those silver dollar sized things, it nearly gave me brain damage...The copper lines, etching, etc is nasty work. My skin used to stay green all the time from the copper dust, and my breath probably smelled like formaldehyde fumes. :/ I had to give it up after a while. The crap was killing me... MK

[snip]

Environmentalists must be realists if they want to be effective: AM
broadcast is one of the lightest footprints in any salt marsh, and AM
stations have very little trouble getting EPA clearance for such places.

FWIW. YMMV.

Bill

I have an existing OCF 80m dipole already set up between two trees (actually the socalled Carolina Windom from Radio Works). I was planning to add a 540' sky wire (square) loop to the farm. One leg of the loop would run approx. parallel to the OCF 15-20+' away. I was not planning to use more than one antenna at a time of course, but wondered if the presence of a "nearby" wire might effect the operation of the (at the time) operating antenna. A nearby wire is another metallic object in the vacinity, what significant effect would this have, if any?

You'd still need a ground radial system, lest the varying water
table constantly detune the array. Also, fresh water is generally
a good insulator compared to copper wire.

With four guys the distance between any two 180 degree opposing guys will be 100' at the base level. That is why I said that four guys at 45 degree angle at the top of a 50' mast will make a square at the four anchor points and that square at the base level is 100' on each side. I am thinking that 30 degrees at the top might be fine for my project in which case a smaller square.

Excellent, thanks, now, what is the rough equation for 'm' vs volume for PCBs?

1776. cell antenna options for remote area???

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-05 00:57:01 UTC
From: coyotefred@hotmail.com
Message-ID: <b8883a35.0405041657.58a1da0b@posting.google.com>
Source record: 95626

Hello!

I'm trying to improve the reception of my cellphone (LG LX5450) on the alltel network in northwest Nebraska to a remote cabin. Within the cabin itself I can only get weak analog reception with frequent call drops. 'Hike up a nearby hill about 200 feet from the cabin, however, and I can a very strong digital signal (the hillside faces the roof of the cabin).

It may be that a decent yagi antenna, aimed properly and mounted on the cabin roof, will be sufficient to get me a good signal. If not, however, I'm looking for options. I could mount the yagi up on that hillside, but the resulting coax run (200' or so) would, I imagine, have me losing more signal than I gain.

I was intrigued by a couple of posts on this group as far as reflectors, "passive repeaters," etc. I'm not exactly sure where my signal is coming from up on that hillside, however...it could be east or north. I guess a little experimentation/aiming with one of these setups would be the key.

But if anyone has been in a similar situation to what I'm describing here and discovered a decent solution, I'd sure appreciate hearing from you.

Thank you for your time.

I hope you are kidding !!!!

Contact the vendors and get a price schedule showing price breaks as a function of layers, area and quantity of boards.

Do you want finished boards, or will you cut boards from a master sheet, etc.?

What level of quality control is required? If you are selling into the NASA or Military market there are VERY SIGNIFICANT documentation, traceability requirements, and QC requirements and certifications required. Even to controlling the exact chemistry of the board material.

Depending on your customer your unit material cost may be buried in recurring paper costs. I'm an expert in this area {Program Chief Engineer, USAF WS-118, RS/RV ... MX Missile]

Bill, that's correct. But, most guying systems are only 3 wires on a 120 degree spread at 45 degrees from the anchor on the tower/mast. That requires only 75 feet. A three wire system is a STABLE solution. A four wire system is also a stable system.

BTW, I used to have a Rohn 25 system at 50 feet. Rohn recommended double guying. First level at the 30 foot height. Second level just below the rotator platform. Point I'm making is that one set of guys at the 50 foot level may not meet Zoning and Insurance safety requirements.

Hi Dave,

Thanks for the info. I am recycling a 50' TV mast, and now that you mentioned the idea of using 3 guy wires, it explains to me why the guy wire rings that came with this old mast have an extra hole on one side (they give you a total of 5 holes). They were providing the option for either 3 or 4 guy wires. On many roof peaks they just tied it to the corners of the building thus using a 4 wire system. Since I will be putting this up in the middle of a field for one of 5 masts to hold a 540' skywire loop, maybe I will just go ahead and use three guy wires like you suggest since it is out in the middle of the orchard and not on a four cornered roof.

In any case, I was previously in error when I said the side of the square at the base of a 4 guy wire 50' tall system was 100'. I meant that the diagonal of the square was 100', making the sides of the square, as was suggested earlier in the thread by Crazy George, a bit under 71' (100 divided by the square root of 2 which is 1.4142... or 100 times .707...

For the 3 wire guy system, I will just wing it and anchor the 3 guys in optimum position considering the position of existing trees in the orchard.

I notice that the local rental yard has a boom lift (Genie), I could just throw a little more $ at this project and be up 40' hoisting and guiding this already assembled mast into place (providing a hinge at the base mount).

Before doing that I will check to see just how hard it would be to lift each section up vertically by hand..... seems like lifting that last section with 40' of noodling extension might be tense. With the boom lift, two people could do this easy one way or another, less tension and less cursing along the way, plus the fun of playing with that boom lift.

I would just like to invite your attention to the Carolina Cyclone screwdriver antenna at www.qsl.net/k4kwh . This mobile antenna packs a punch without "punching" a hole in your wallet! It is made of the finest materials available--such as the loading coil. It is made of black nylon and is grooved to exactly fit the coil windings and
not "jump" out of place. Your loading coil will not wiggle around inside the mast more than 1/32 of an inch; it is precisely machined to fit the mast even when fully extended. Check out those "flimsy" weather covers that
flex with a squeeze. In a year, you'll be looking for another one because it will have split and cracked under the UV rays! The Carolina Cyclone come with covers made of 1/8" wall Lexan. NO cracking and splitting here! It will last for many years.

Don't be afraid to run 1000 watts SSB on Carolina Cyclone I, or 1500 watts on CC II!

Compare the price, too. Nowhere will you find this kind of value and performance for the price!

Visit www.qsl.net/k4kwh for photos and info.

On Tue, 04 May 2004 12:46:02 -0700, Jack Twilley
>I recognize that salt water is far more conductive than fresh water,

Hi Jack,

Unfortunately, this is a persistent illusion that begs real comparison to real conductors. Salt water is miserable as a conductor, and its special place in the pantheon of noble applications has little to do with "conductivity."

>but fresh water's still superior to sand and the like.

Even this is arguable, sand has less loss (as sand is one of the most common precursors to making glass, it is hard to suggest it presents issues of conduction or loss).

> That being
>said, I am wondering about using a pond as a ground screen and
>mounting the antenna itself on an island (or a raft) in the middle of
>the pond.

No doubt you will get a raft of anecdotal support, but not much data.
>
>What I don't know is just how large a pond do I need in order for
>something like this to work?

I will do something dangerous and make a presumption. To work, as you suggest it through the example of the AM stations, you need to be operating in the 160M band. OK, so that was a caprice of guesswork, the remainder of your post offers other opportunity to suggest you are building your house on sand.

>For those who absolutely require less variables in their equations,
>imagine a standard dipole tuned for 20m strung roughly 45 feet above
>ground level between two trees, one on either side of a fresh water
>pond.

Well, this is where you are in over your head (water metaphors are abundant in this topic). This, again, requires presumptions insofar as the original observation was driven by the AM example. However, at this point we will depart from the low frequency mandate to examine another mandate: polarization and your presumption of conductivity.

A horizontally polarized antenna seeing a horizontally conducting surface is a scenario that describes a self-short-circuit. Horizontally polarized waves meeting the earth (a conductive one) immediately snuff themselves (how long would your car battery last

with a screwdriver held across its poles?).

On the other hand, vertical antennas do not suffer this fate - and for the same reason: it is a current wave (or at least the magnetic component inducing such a current, in a conductive earth) that spans earth making a perfectly reasonable relationship to continued propagation.

>How wide does the pond have to be at that point (and others)
>for it to work right? Even answers like "the pond will have to be
>wider than the dipole is long" or "there will be no noticeable impact
>on performance" are fine if they're based in reality, and ideally in
>math and physics I can understand.

Well, once you divorce yourself of the notion of using a horizontal antenna, it becomes a matter of "ray tracing" from the vertical polarized source, out to the reflecting surface. If you want a radiation lobe to bounce away at an angle of 45ï¿½; then this surface has to be as far away as the origin of the ray's source is above ground. If you want a radiation lobe to bounce away at an angle of 5ï¿½; then this surface has to be 10 or 20 wavelengths away (which is why large bodies of water are so attractive).

OK now to drop the other shoe.

The reason why this all works can be described through conduction, but that is messy and far from intuitive (why is a poor conductor better than a poorer conductor that is sometimes better than the poor conductor?).

The whole matter of near earth conductivity (through the application of trig) hardly matters a whit in regard to DX angles. DX angles are a property of the earth in the far region (at least 5 wavelengths away, which describes the almost certain frustration of planting long enough radials that will make any difference in that regard).

The trick is to simply abandon the thought of the antenna except as a point representing the source of the ray to be traced to ground. Think of the wave propagating along that ray. It has left the antenna far behind and is in its native media of 377 Ohms. It then happens to intersect another media - salt water. Salt water's characteristic Z presents that wave with a 10:1 SWR mismatch, and as we all know exceedingly little power passes through that interface, and nearly all of it is reflected (again, in the same angle of reflection already described by the ray we started with).

THIS is the power of salt water, marsh water, and other so-called conductive surfaces. The conductivity is for s**t and matters just as much - it is mismatch that does our work. Even average earth presents a mismatch, but not nearly so effective; thus power passes through the interface at its critical angle (another optics concept that is intimately tied into this ray-tracing). We call this (as does the optics community) the Brewster Angle. Optics has a simple method of

forecasting the angle, and it is the same math that gives us SWR. a ratio.

Well, there is more that could be said, but this is enough to part the waves.

Hi Group,

Many thanks to the folks that posted a message for my FM trap question.

I been studying the traps made out of coax for several years, they all form a parallel circuit.

Is there any way I could connect the inner conductor and braid such that I form a series circuit. I want to pass my signal not keep it in.

Now you're talkin', Bill! ;-) Just don't expect that lift to have much work left in it when it's mostly extended, especially with two men in the basket.

Just a note on high winds effect on light gear: It might save you some repairs to add a very light guy wire in the general direction that summer thnderstorms throw line squalls at you. Add that as near to the antenna itself as possible. After seeing one or two storms a summer shake some elements pretty hard, I noticed that our 50-60mph line squalls _always_ blew in the same direction (within 10 degrees every time). Adding one single (high) guy wire fixed that problem, as it stopped the whip-sawing action that a good blow will do to any light gear, no matter how well it's mast is guyed.

I have a differeny "brand" of screwdriver that has a flexible weather
cover that has been out in the sun for several years.. and its still as
good as it was the day i bought it. AND for the price of the cyclone i
could have bought the antenna I did.. and one of the new automated digital
controllers for it.

Contact Altel and ask them where is the nearest site to your cabin, and in what direction.

There is also the chance that you can get to talk to a friendly person who can give you suggestions as to an external antenna.

1798. Wire antenna - dipole vs inverted vee

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-05 14:47:24 UTC
From: "Larry Gauthier (K8UT)" <MyCallsign@ARRL.NET>
Message-ID: <109hvjum3c6qba7@corp.supernews.com>
Source record: 95647

I have always been of the opinion that when it comes to wire antennas, the prevailing rule of thumb is "the higher the better". However, I am about to deploy a 270' 160m antenna, and -- based on available trees -- I can either install an inverted vee with a 50 foot apex, along a straight vertical plane, with ends dropping off to about 15 feet high; or a dipole at 50 feet, with the antenna in a straight horizontal plane (center and ends at 50 feet), but the vertical plane in a V beam configuration of about 90 degrees.

I enjoy chasing DX - so which configuration should I choose? Would the slight vertical component of the inverted vee offer me a better take-off angle than the horizontal dipole? Or should I opt for the "higher the better" route?

Thanks in advance for your responses,

-larry

1800. easy way to refurbish tarnished copper wire?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-05 15:16:32 UTC
From: Larry Gagnon <lagagnon@fakeuniserve.com>

I need to solder a new section of 14 gauge copper antenna wire to a very old section of wire that is highly tarnished and very old. Other than pulling each strand apart and attempting to sand off the tarnish is there an easier way to remove it so that I can solder it effectively?

You aren't the first to think of that idea, and if you stick around
the newsgroup long enough, you will find you are not the last! It's not
a dumb question -- the only dumb question is the one that isn't asked.

When I think of something I haven't heard anyone else discuss, and I
haven't seen mentioned here or in other online fora, I try to research
it a little online and see if I can learn more about it. With this
one, it was too tempting (because of the AM example) and the stuff I
had read about Sommerfeld grounds in the NEC2 source and also comments
seen on Mr. Cebik's site (usually associated with graphs of antenna
patterns made with different types of ground) led me to believe that a
quasi-infinite plane of salt water goodness would be a huge boost. It
sure beats placing a layer of aluminum foil or steel plate over the
backyard. ;-)

From: 'Doc <w5lz@cwis.net>
Message-ID: <40990DF3.D1EF4C0D@cwis.net>
Source record: 95653

Bill,
The proximity will distort the radiation pattern of
the antenna in use, slightly. If the loops is used on
80 meters, the OCF antenna will 'rob' a little signal,
and visa-versa. I don't know if I'd call it significant,
though, probably not...
'Doc

Jack,
Depending on how difficult errecting the thing would be,
why not give it a try anyway? The water may not 'help' a
signal, but the antenna being away from nearby 'stuff' might.
If you have the wire, a pond, a boat(?), etc...?

Don't laugh, but I did put up a mast with only two guys, and I don't mean the guys that helped me in my madness. I was thinking that the antenna wire would act as the third guy. Bad idea! OK, dumb. Now I am having to do a work-around pulling up another rope taped to the one rope I was going to use to hoist the antenna, so I will have an extra rope that I can use as the third guy in addition to the rope that would hoist up the antenna. I will be happier when I am out of all this hot water.

I am told that soaking the wire in vinegar with a little salt added shines it up nicely. This was a recent Hints and Kinks item. Buddies tried it and say that it works. Seems to me that vinegar alone might work, too. Good luck!

Oh, those "pony clamps", I have a shop full of them, but I don't quite yet get how to use this tool to pull up a section of mast which is nearly 2 inches in diameter, although I do see how such a device might be something related to the problem, I will have to think about this. Maybe put this clamp on a 15' piece of pipe down to the ground and use that ratchet section somehow...?

Other related tools around the farm: the "tractor" jack, you know the kind of jack you use to lift the side of a building from the outside, or that same jack with a short twist of chain used to pull up old metal fence posts out of the dry ground. These jacks are heavy and about 4' tall, but theoretically there could be a way to employ it to yank up a section of the telescoping mast, but the whole image of this seems awkward to me.

Another related, antiquated, and obscure tool would be a type of jack that is used when pulling a long pipe out of a well. It clamps around the pipe as it is being pulled up and has a rachet so that the pipe cannot slip back down the well while you adjust your grip for the next pull. Each 20' section of pipe is pulled up and disconnected so the next section can be pulled up. Unfortunately I sold this at a local flea market years ago thinking I would never need it again. Truth be told, I didn't even know what the thing was at the time, it was something in the barn when I bought this place in '74, so when I cleaned up the barn I unloaded a bunch of stuff. The old timer who bought it at the flea market told me what is was for.....D'oh!!!! One man's junk=another man's treasure..... maybe I can track him down and buy it back....it is probably lying around in another barn somewhere.....

Meanwhile that 2HP electric submersible pump down 240' has been working for at least 40++ years! Had to have it pulled up once to replace the wires. They don't make things like that anymore!...you should have seen this thing, all brass pump section 4' long, and then the 2hp motor section which seems indestructible, knock on wood....

Still have the old wire (which was replaced) out in the barn, three 240' lengths of solid #10 insulated copper (with a few places where the insulation broke down)....now there is an antenna project waiting in the wings.....either that or some nice pennies at the recycling yard....

> effectively?

Larry, try a solution of sulphuric acid (avalable at retail) for cleaning and preparing copper joints for soldering. This has been used in plumbing/pipefitting trades for decades to make a clean joint for soldering. It should work as well on stranded copper. From your description of the old wire condition however, your efforts would be better served by just replacing the old wire and using all new material.

Hi Bill

I was using the Pony Clamp as an example only.
It is a woodworking tool used to hold boards together for gluing or whatever.
The way the Pony Clamp device grips the pipe on the floating end is roughly similar to the way the twin grips grip the mast for more secure lifting than using a pair of gloves and brute strength.

A fellow ham used a similar technique, He made a small platform at the top of the lowest mast that supported a simple hydraulic jack.
The piston of the jack was used to elevate the upper masts about 6 to 8 inches at a time, also using a holding device on the upper mast being raised similar to the Pony Clamp holding device.

However, to make them removable, instead of being a few pieces of steel plate with a hole in them. They are more like a pair of "F" shaped plates that lock on top of each other.

The idea is to be able to hold the mast being lifted securely so it doesn't slide back down.

An alternative of course is to THREAD each section of the mast and install external pulleys and internal glides and make it a crank up tower.

Hi Bill

Tilt up is a GOOD way to go, if your pole is strong enough!

Did you know that you can get heavy guage aluminum light standards from your local street department that have been hit by cars. Or sign masts from local sign companies for a very fair price? (Often the price is the price of the metal as scrap).

At my old house, I had a 45 foot tilt up light standard. I mounted it near the eave of the house using a steel standoff to lock it to (even though it didn't really need it). A small boat winch was mounted to the roofing rafters and the cable fed through the facia board to the winch.
On top of this 45 light standard, I added an additional 10 foot section of mast tubing.
Had no trouble at all putting it up or taking it down and it needed no guys at all.

I am sorry, I don't remember getting an email from you, would you
kindly re-send. Thanks. Could you kindly put 'PCB costs' or
something along those lines in the header because (as you can tell)
this is my spam email account.

I have gotten pricing from the reps (before I started this thread),
but until you are ready to sign on the dotted line and sign up to the
volume the pricing is not accurate (budgetary pricing), so once again,
so far I know the MOST I am going to pay.

I am in NO WAY trying to undermine the substrate industry, on the
contrary, I am just trying to figure out that happy point at which
BOTH they and I make money. If you look at my above posts I fully
expect and want them to make a profit, but not too much profit (BTW
there is no such thing as 'too much profit', I, like them, am trying
to maximize mine). Remember, I am asking for the lowest price at
which they ARE willing to do business. Once again, I CAN'T get that
price until I am ready to sign and I can't be ready to sign until I
get that price.

1817. Loop Antenna for Class-E amplifier

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-05 21:46:57 UTC
From: Marc Battyani <Marc.Battyani@fractalconcept.com>
Message-ID: <c7bn90$eed@library1.airnews.net>
Source record: 95666

Hello,

I've made a Class-E amplifier which works rather well as I get 25VRMS into a 50 Ohm resistor.
But heating a resistor is not really want I do ;-)

I want to send this power into a loop antenna to transmit power by induction to another aantenna 10 to 20 mm away.
The transmit loop antenna is in series with a capacitor and the receive antenna is in parallel with a capacitor. Both antennas are tuned to the correct frequency.

The problem is that though I have 125Vpkpk at the transistor drain, I only have 15Vpkpk at my loop antenna and also 15Vpkpk in the receive antenna (not loaded)
I guess I need to to some impedance matching but how do I compute the impedance of those loops antennas (is it just the L//C ?) and how do I compute the output impedance of the class-E amplifier ?

Any suggestion, URL etc ?

Thanks,

Marc Battyani

Richard,

Are you sure you meant the statements quoted below?

Horizontal polarization bounces just fine from "horizontally conducting surfaces". Indeed, when a mixed polarization wave hits a conducting surface the horizontal polarization in the reflected wave is enhanced, not "short-circuited". This is the same phenomenon that is the related to Brewster's angle.

Perhaps you really meant to say that a special guided wave mode, namely the ground wave, does not support horizontal polarization.

If you just want to pass your signal, what's wrong with just
connecting the coax from the source to the load?

Or do you also want some filtering? If that's what you want, consider
two stubs. (Actually, a single stub is generally not a very good
filter...) These two will be attached to your feedline at the same
place. One will be shorted on the other end, and the other will be
open on the other end. Their total length will be 1/4 wave
(accounting for the line's propagation velocity). So you're feeding
your line through a 1/4-wave resonator, tuned to your signal
frequency. But the shorted part will reflect back a short at some
frequency, and knock that one out. And the open part will do
likewise. And you can so a similar thing, but with different notch
frequencies, if you use a half-wave resonator open on both ends, or
one shorted on both ends. The key is all these will pass the
frequency the resonator is tuned to. Beware of resonator losses if
you tap way down on it.

RFSim99 is a good tool for playing with this sort of thing. You can
readily see the inevitable harmonic responses that occur with stubs:
things tend to repeat at even and odd multiples of lowest resonance
frequencies. But you can get more accurate results by including the
line loss in your calcs. There are generally only a few "intersting"
frequencies to check, easy to do in a spreadsheet for example, using
accurate line equations.

There are lots of other configurations that can do interesting things,
too...you can make a harmonic filter out of series pieces which
alternate impedances above and below the main line's, for example.
It's not very easy to insert a stub in series with a piece of coax,
but I've seen examples of that with balanced line.

Cheers,
Tom

Hi Jack,

Let's not lose track of why this is true, rather than fixating on the
downside of alternative illusory explanations. We have DXers here
frequently gushing about their shore installations.

We also had reports from one fellow who maintained a regular schedule
with an Aussie who worked CW mobile in his car coming home from work.
Our man here could literally see the variation in signal strength as
he approached or moved away from the shore down under.

Now, this report is typically known as anecdotal. However, when you
can repeat the observations and correlate them to your hypothesis (as
they did), then such reports gain materially.

Hi Gene,

Vertical polarization is the only mode that the Brewster Angle works
for (that's why polarized sunglasses work so well, they are
contra-polarized for what DOES reflect).

To test your hypothesis, use EZNEC over a perfect ground and note the
distinct difference at low angles (less than 5 degrees). The
horizontal radiation lobe is an example of Lambertian (another Optics
term) distribution where the maximal gain is observed directly
overhead, and only when phases positively combine (due to the high
surface conduction presenting a second source). Other phases give
rise to this Lambertian distribution which is much like the lobe
characteristics of a headlight glowing in the fog.

Source record: 95572

passive repeaters are a very specific application, that likely won't work in your case.

Let's say you have a -70dBm signal at the hilltop (that's fairly strong for either analog or digital). Even with two 10dB gain yagis (one pointed at the cell site and the other pointed at your cabin), the signal sent down (from the "passive repeater" is starting out at -50dBm (-70+10+10, ignoring connecting cable loss). That's compared to a power radiated of +50dBm at the cell site.
Anyhow, if the hill is 200' tall and 200' away, the space loss from your "passive repeater" to your cabin is another 70dB or so, for a final signal of -120dBm--too weak to be of any use.

On the other hand, 100' of cheap RG-58 loses about 14dB/100ft at cellular, a 300' run would be -42dB, and if hooked to a yagi on a hilltop gives you -70+10-42=-102dBm at the end of the cable...weak but probably usable. Problem is, it would have to be connected directly to the phone. Not very mobile at that point :-) The instant you hook up an antenna (to reradiate) you will lose at least 10dB right off the bat (the first foot of distance from an antenna at cellular is -22dB space loss).

You could get lucky though...if the hilltop signal were -50dBm (that's pretty damn strong) and you splurged on 15dB yagis, you'd end up with -50+15+15-70=-90dBm which would work fine.

I might add, compare this horizontal's low angle performance to its
free space performance (a world of difference from that nearby
"conductivity" and none of it remarkably "good" even for the most
perfect of grounds). You have to hoist your horizontal pretty high to
bring the phase gains into play.

Richard Clark wrote:
"Salt water is miserable as a conductor, and its special place in the pantheon of noble applications has little to do with conductivity."

I praise the god of conductivity for the ocean`s behavior as a beniign enabler of medium wave propagation over extraordinary distances as compared with ordinary earth. The reason the ocean`s surface allows long distance propagation is explained in part on page 15 by Ed Laport in "Radio Antenna Engineering":

"Nothing can be done about the electrical characteristics of the grouind or topography between transmitting and receiving antennas. By choice, it is possible to locate the antennas in areas of the best available soil conductivity, thus to increase the terminal efficiency to some extent, and to increase this efficiency still further by proper design of the grounding system. (For ground waves vertical systems are imperative as there is zero horizontally polarized ground wave propagation.)

Optimum ground-wave propagation is obtained over salt water because of its conductivity (many times that of the best soils to be found on the land) and uniform topography."

Laport has a ground-wave propagation table on page 17 of "Radio Antenna Engineering". It is for low frequencies which best exploit ground-waves.

At 1000 miles over seawater, a wave at 400 KHz is attenuated by 98 dB. Over good soil, 111 dB. Over poor soil, 160 dB.

Soil resistance determines penetration depth nto the soil and loss that the soil extracts from a wave, especially if the frequency isn`t too high. At 10 MHz and above, over real earth, the earth`s capacitance offers so much less opposition than the earth`s resistance that the earth`s resistive opposition really does have very little to do with conductivity. However low the soil conductivity is, it is effectively bypassed by the earth`s susceptance.

Sea water is so good at limiting medium-wave penetration and loss that broadcast stations can be heard far out at sea during daylight hours. This range is much greater than over any type of land. I recall hearing the steel guitars of Hawaiian music when we were approaching from the U.S.A. during WW-2. We were still days away and the sun could be high in the sky. It wasn`t all that far as we only traveled about 250 miles a day in good seas. Field strength increases by 6 dB every time you cut the remaining distamnce by half as you approach the station. At half the distance the volts per meter double.

Best regards, Richard Harrison, KB5WZI

"---I was commenting on your assertion that the horizontal polarization is "shorted out" at a conductive surfacce."

Richard Clark`s description may be indelicate but as I recall, Terman says rouighly the same in several instances. Wish I had a copy at hand. Terman says that a horizontally polarized low-angle wave suffers a phase reversal upon reflection and as the difference in path length is negligible between incident and reflected waves at low angles, the waves being of opposite phase add to zero.

There are active Cell phone "repeaters" bricks, not sure what band though
(AMPS I'm sure of), and you would need power at either end.

Fred:

Make a corner reflector screen. Nothing fancy, for this frequency a couple of square screens a foot or so in size. Put them together at right angles, put the cell phone at a point which is a quarter wave from both surfaces (dimension depends on band), and point the whole mess toward where the signal might be coming from. Watching the "service available" light should be informative for initial tests.

Indelicate or blunt, the results are the same. The Lambertian distribution of a characteristic that is painfully 30 dB down due to the presence of a perfect conductor plainly evidences severe loss. It can't be the ohmic loss of conduction as this would negate the premise of a perfect conductor, it can't be the dissipation factor of an insulator for the same reason.

The electric dipole moment is clearly bridged by a conductor, by definition. As such, at the interface, it must collapse completely into a current which gives rise to counter emf, the two waves cancel as a function of phase - the proof again is found in the Lambertian distribution that vanishes completely with the removal of ground (why horizontal antennas are held up in the air). The more remote the ground, the greater the variation of phase and the distribution, and yet the low angles never fully recover (the death embrace of ground is always there).

The ONLY deficit the vertical sees is in the characteristic Z of the interface presenting a Brewster Angle that allows unfettered passage of power through the interface and traps it. Again, it is the ratio of the characteristic Zs that account for this. If you could contrive to find an earth characteristic of 4000 Ohms instead of Salt Water's 40, then you would observe the EXACT SAME characteristics of propagation. The poorest earth almost looks like the Z of the ï¿½ther. This means that the power impinging upon it is trapped (because ray tracing would reveal it trying to penetrate the earth to re-emerge in the antipodes). Hence the conduction explanation is a contrivance that fits only through the imposition of a limited experience.

Replace the perfect conductor of an imaginary world with that of a realistic earth and the Horizontal's low angle response still sucks to the tune of 30dB down (for the terminally anal, perhaps closer to

-26dB). This says Horizontals suffer for the same reason irrespective of earth conductivity (unless perhaps you are on a mile high mountain of glass). In some sense, this suggests that at least you don't have to worry about it too much because there is nothing you can do about it (although I have disproved this too).

On the other hand, for verticals, the variation of earth characteristics gives rise to a wide variation in low angle response. And for some earth characteristics, the vertical is clearly the winner by an order of magnitude (dare I say in excess of one S-Unit?).

Is this boon conduction borne? If Salt water with a pathetic conductivity orders of magnitude beneath nichrome wire is superb, then by the facile logic of conductivity, we should see remarkable performance boosts for a plain of silver. No, the conductivity argument is simply the tales we tell frightened children who awake from DX nightmares. ;-)

MOUNTING those antennas spaced 8 to 10 feet is about right.
Stacking, applies more to two similar antennas for the same band and switching them for vertical pattern control.

Richard,

I am well aware of the properties of the phase reversal, cancellation of direct and reflected waves, and so on. I have no substantive disagreements with Terman.

I suspect Richard Clark was exercising a bit of poetic license by stating that the horizontal polarization was "shorted" at the conducting ground plane, perhaps in a vain attempt to simplify his explanation to the original poster.

However, this statement is simply wrong. If it were true there would be no NVIS nor any reflections at all from a normal incidence wave on a conducting surface. Radar would not work. Mirrors would not work.

Wave cancellation is not such a difficult topic (except on RRAA). There is no need to invoke phony arguments about waves "shorting".

Isn't that the definition of Catch-22??

Seriously, you need a sit down negotiation session with your potential suppliers, AND HAVE YOUR PURCHASING AGENT/LAWYER PRESENT. Part of your strategy is to let your potential suppliers know right up front that it is a competitive procurement based on either lowest price or best value [whatever your criteria may be][The stated criteria is common to and binding on all potential suppliers [you can't change the rules without inviting a rebid from all suppliers]]. In my experience, once we moved from the technical issues I yielded all related business risk issues to the Purchasing Agent or Lawyers. Engineering should NEVER sign a purchasing contract. The US DOD and my company used legal professionals to definitize the purchasing agreements/contracts.

Review your potential supplier's quality programs, manufacturing capacity, inventory levels, their supplier vulnerabilities, [you don't want your long term sales jeopardized by a sub-supplier's strike etc.,], cash flow requirements [do you make a partial payment up front or is it post delivery billing], backlog [you don't want your schedules held hostage by a supplier's backlog issues]; these are business issues that exceed 'lowest price' criteria.

Negotiation is more a part of business than creative design. In many MBA programs there are courses in negotiation. Remember, your supplier NEEDs business; and, wants to MAXIMIZE their profit also.

Richard, would the dipole's performance thus be improved by bedding the ground with sand, and hurt by adding ground radials? Same true if the dipole was at some compromise between 1/4 wave and the desired 1/2 wave above ground?

Regards,

Jack Painter

Great info again Richard,
I recall during my early days in the Navy of
being able to listen to AM radio stations from Victoria B.C. all the way to
Hawaii. I always attributed it to the salt medium, but never really knew
enough about antennas and propagation other than to tell myself that salt
water was a better conductor.

When you think in terms of 'salt water because of its
conductivity (many times that of the best soils)' and then show the differences
in terms of Db attenuation it all makes sense.

This applies in many areas of discussion on this newsgroup. One worries
about ideal height above ground, transmission line losses, radiation pattern, etc,.
whereas the main objective is to get a signal out in the ether one way or
another, and damn the technical naysayers, full speed ahead.

Even with a limited knowledge of antennas and propagation, which thanks
to the knowledge gained on this newsgroup, I have always managed to get a signal
out of the shack and into the air without regard to the warnings of the pundits,
and thoroughly enjoyed making contacts -- many DX -- blissfully unaware of
how effective or efficient my antenna system may have been!

It frequently troubles me that when a novice asks a simple question
about antennas they are often distracted and possibly prevented from trying
something because of theoretical albeit often practical arguments against.
If you don't get the wire out there, you don't get the signals out either.
60db attenuation still beats infinity, and on a clear day you can hear
forever!

By golly, maybe I should rethink salting the back 40! :-)

Richard, would the dipole's performance thus be improved by bedding the ground with sand, and hurt by adding ground radials? Same true if the dipole was at some compromise between 1/4 wave and the desired 1/2 wave above ground?

Regards,

Jack Painter
Virginia Beach, Va (where mostly sand exists anyway)

ps Mr. Fractenna, your motives are transparent and the games you are
playing are obvious to everybody. From your initial post it was clear
that you were going to be less than helpful. Now, I am asking you for
the SECOND time, please GET OUT OF THE WAY. That means kindly refrain
from further postings in this thread. Thank you.

In case for some reason you choose to continue this pissing contest
via email, wasting my time, I reserve the right to post your emails on
this board.

Best of luck.

1849. FDTD in Matlab or C

Hello all the FDTD experts over there ,

I am starting out on my class project which requires me to write
a 2D FDTD code.I am thinking of doing it in Matlab or C.Matlab would offer
good user friendliness but I have heard that Matlab being an interpreted
language is quite slow when it comes to loops.My requirement is about 4000
cells utmost (200 x 200) and time step of the order of 1 Pico second.Will
Matlab be very slow that I should consider coding in C or will Matlab do
okay with respect to the execution time.

-Warm regards

I see someone is selling some stronger yagis on eBay (40" (spec'd at 24dB) for $100 and 60" (36dB) for $130). Assuming those specs are reasonable, from your math here it sounds like I might end up "OK"...

My other problem is connecting any external antenna to the LX5450. Apparently the external antenna jack/port is so weak that people are breaking their 5450s (the internal soldered connection to the on-board stubby retractable antenna) when they try to plug in an adapter, that no one is making any adapters for this phone. I don't know if a "clip-on" adapter would work for something like this. It seems like someone could craft something that would work here...

Someone had also suggested I look into one of those "signal boosters" or "repeater amplifiers" sold by Wilson and others for $350-$500 (that apparently boost your signal to the max 3watts). 'Kind of expensive...and would the result be comparable to the external antenna options we're discussing here?

Hi Jack,

A good question, and one that brings out the one of my elliptical
statements about having disproven you don't have to worry, because
there is nothing you can do.

In fact you can do something, however, it separates the discussion of
ground insofar as near field and far field issues.

IF you add a ground screen below a horizonal antenna, you CAN improve
your communications efficiency (your contact, with sufficient
resolution, could see an improved, stronger signal).

This, of course, has no strength in its argument in the far field, the
same problem exists of the complete collapse of the electric field
through its polarization giving rise to a canceling current. The near
field application (where the media does NOT exhibit a 377 Ohm
characteristic) is one of shielding the source from loss (which is
largely a dielectric loss, not a conductive, Ohmic loss).

Richard Harrison, KB5WZI, has already recalled Terman's treatment, but
having no reference handy, he hadn't really pulled it together.

The point of the matter is that for a conductive ground, the electric
fields are laid across a short. The obvious occurs and that electric
field collapses into a magnetic field (through the short circuit
current that necessarily follows) at the interface. This simple

statement is enough to evidence the reversal of fortune (magnetic replacing electric in the face of its initiating source spells short circuit city).

At a distance (along the magic 0ï¿½ DX launch angle), BOTH the source and its reflection (or image) in the ground below it, are at an equal distance to the observer. Thus the distant observers (if they could) see TWO sources that are 180ï¿½ out of phase. Thus everywhere along this meridian, those two signal completely cancel. With tongue in cheek, let's call this 100dB down. This happens ONLY for horizontal polarized signals. By shielding ground beneath the horizontal antenna, you are doing nothing to change this star fixed fate; but you are improving efficiency with a net positive gain, relatively speaking. You simply have two stronger signals canceling.

At higher angles, lets call them 5ï¿½ or higher (sometimes much higher) the path lengths of the two sources diverge from equality (a phase shift is introduced) as the signal strength attempts to pull toward the free space value, some 30dB higher. If you pull your attention successively higher, you eventual come to the point where the two path lengths introduce enough phase difference that they combine to a net signal that is greater than the free space value. This, by the way, does not constitute DX opportunity and is crowed about as the great NVIS advantage (in other words, the sufferer has no options and is content to make lemonade). This exercise describes the Lambertian distribution, a classic example of Optical sources.

Raising the horizontal is much the same gain story. It removes itself from the cold embrace of earth's loss, and it introduces a new phase combination. Thus the lobes may lower from the Zenith, but you will never see them pulled all the way down to the horizon, such is the fate of horizontality. ;-)

>I have a Hustler amateur mobile antenna model RM-80 for 80 Meter 25-30 KHz.
Can
anybody tell me the length of the counterpoise needed for this model?

A 1/4 wave counterpoise would be about 65 feet or 20 meters. Mobile antennas use the vehicle body as a counterpoise. Your 65' wire or a vehicle used as a counterpoise will not produce very good results, because the efficiency of the short radiator is only a couple of percent.
As an option, a really good performing portable 80m antenna that I have used many times is an inverted vee supported by one of those 33' fiberglass poles. It is fed with 450 ohm line and a tuner. The vee is 50' (15 meters) per leg. You will need about 80'-90' to spread the vee. That's a lot of space, but you will need 65' for the counterpoise for the Hustler. It will beat the Hustler-counterpoise idea significantly, and you can QSY all over the band. With a Hustler you have a narrow bandwidth.
Good luck and DX.

Don't think about it, do it. You'll find out soon enough if it's too slow.

I did one several years ago using the interpreted Visual Basic that comes with Excel, letting Excel do the plotting. It seemed to update pretty quickly. Matlab would probably be fine. C is great if you're comfortable with plotting, otherwise you might spend all your time fighting the interface. Here are some references, if you're interested:

References:

1. R. C. Booton, "Computational Methods for Electromagnetics and Microwaves" John Wiley & Sons, Inc. 1992. This text gives an uncommonly clear presentation of the basic theory, although it lacks enough detail to set up practical problems of the type that we selected. The FDTD section discusses primarily 1- and 2-dimensional problems.

2. K. S. Yee, "Numerical Solution of Initial Boundary Value Problems Involving Maxwell's Equations in Isotropic Media," IEEE AP-14, 1966. This is the classic paper to which all subsequent writers refer.

3. Sadiku, "Numerical Techniques in Electromagnetics." This book provided a good level of detail for setting up FDTD problems. It provides a good indexing scheme that makes for efficient implementation of Yee's algorithm. This book also gives a limited discussion of absorbing boundary conditions and briefly discusses options for feed waveforms. There is also a

brief note about reducing run times by filling the space with a low conductivity, therefore reducing the effects of multiple reflections.

4. Omiya et. al. "Design of Cavity-Backed Slot Antennas Using the Finite-Difference Time-Domain Technique," IEEE AP-46 Dec. 1998. This paper provided some more detail on the problem setup, showed sensitivity of accuracy to the number of time steps, and discussed a windowing technique that could be used to shorten run time. It seems that this windowing in the time domain ends up being quite similar to Sadiku's introduction of loss in the cavity. The mathematical operations are very similar, even though the justifications are different.

5. The Internet site "FTDT.org" has some good information and programming examples. The content matches the information in the above references, with more effort put into formatted output.

6. Jeong Phill Kim, "FDTD Basics and Programming Tips," March 22, 1999. This is a very clear, concise treatment of the subject with sufficient detail to begin a practical analysis.

7. R. J. Luebbers and H. S. Langdon, "A simple feed model that reduces time steps needed for FDTD antenna and microstrip calculations," IEEE AP-11, July 1996. This paper describes a feed loading technique, used by Kim in reference 6 that greatly reduces the convergence time.

8. Cheng, Dib, and Katehi, "Theoretical Modeling of Cavity-Backed Patch Antennas Using a Hybrid Technique. The configuration studied in this paper is similar to the one studied in the final configuration of this study.

9. Balanis text, "Antenna Theory Analysis and Design," 1982, Harper and Row. There is a good description of the application of Huygen's Principle on pages 447-456.

Anyone selling a 60" yagi with 36dB at 800MHz is a liar :-) It can't be done (5' tall panel antennas on top of the base stations are only 12dBi).

The "signal boosters" can work. But it still needs to go up top of the hill; if there isn't enough signal at your cabin for the phone, there isn't enough for the booster to start with. And then you'd need power and weatherproofing up there.

The signal boosters work great for AMPS, but not necessarily for CDMA (you mentioned Alltel so I am guessing that's their digital service in NE). In fact I don't believe the FCC has type-accepted any CDMA signal boosters for subscriber use.

Are you using a switch mode power supply to run your radio's?

You can get modulation products produced by switching noise on the supply rail.

Regards

Robin Cassidy

You can compile Matlab code as one of the options at least in Version 6
That speeds it up considerably. You can handle matrix maths without
element by element addressing - I don't think C does that.
I'd use FORTRAN myself :p

Try throwing up on you battery terminals; I think you'll find that your gut contents are more acidic than Coke.

If you want some serious acidic cleaning, just buy some Muriatic acid at the local hardware store, typically only about $5 per gallon. This is really hydrochloric acid, and does a really great job removing rust from steel or corrosion from other metals. Be extremely careful, this is as active a cleaner as you can readily buy. Use it full strength. The fumes are dangerous, and it works fast, sometimes too fast. Get some old Pyrex trays and bowls to work in, and get a pair of long barbecue tongs to hold your items.

Not enough danger in HV or RF? Then expand into chemistry!

You may think you do, but you really don't..:(Well, maybe if you like
radio torture sessions where 100w out works like 5w...:(Only if you
were at the beach on salt water, or had 60 or more radials under it
for a normal ground mount, would I give it an estimate of doing a half
decent job.

can
> anybody tell me the length of the counterpoise needed for this model? or can
> I just use an earth wire>

As noted, a 1/4 wave is appx 60 ft, but one radial is nearly useless
at reducing ground losses on a ground mount vertical. And being the
vertical is short, and fairly inefficient, the need of a *good* radial
or ground system is extra critical.
On a car, you just take the ground losses and deal with them, as there
is no real choice. But the hustler antenna in itself, is not the best
in the west. The coil is fairly lossy. But on the other hand, with one
radial, ground losses would likely overshadow coil losses, and it
wouldn't matter. :/ What is "portable" going to be? When I run
portable, I just string up a quicky dipole, or use my mobile antenna
thats on the truck. But my mobile antenna is a good bit better than
the hustler...Less coil loss. It's a fairly usable system even on 80m.
But I string a dipole in some trees if I want a *real* signal. I also
have two of those "drive on" mast holders that you park a wheel on. So
I can actually put up masts quite easily portable if no trees are
around.
I use those cheap 10 ft fence rail sections as mast. Two gives 20 ft,
and can be put up easily by one person. Three is too top heavy unless
you use extra guying precautions..I've tried lifting three together
once, 30 ft" and it was kind hairy...So I just stick with 20 ft
worth. It's good enough for the average NVIS stuff I usually work on
80m. MK

Neil,
By now, you have probably figured out that the 'Hustler'
antenna as a portable isn't exactly the best idea without
a very good ground system. But, it will work with a
counterpoise. Not well, but it will work. Something in
the near 'neighborhood' of a 1/4 wave for the counterpoise's
length should make the transmitter 'see' a load it can work
into (depending on how that counterpoise is 'laid out').
There are other options for a portable antenna that may
work better than an extremely shortened mobile antenna...
'Doc

Why do switchers have such a reputation in ham radio?

I realize it's possible to hose up a switcher design pretty thoroughly, (you can also make a 7805 into about a 2W transmitter on 160M if you're not careful), but I've never seen the sorts of problems that I keep hearing associated with them..

BTW, I design switchers, and use them for power supplies in low noise systems, without shielding or other expensive "voodoo" of any kind.

When designed properly, they are very efficient, and very nearly "silent".

1) Leakage Inductance from the core allows a small magnetic field to be
radiated.

2) By their nature they require a 'small' ripple voltage to exist on the
output as a consequence of the switching principle.

3) The input power, the raw power, is being modulated by the switching
cycle. This generates a transient pulse power on the input lines that
easily couples noise via various susceptibilities into the receivers.

4) The variable switching cycle, or the varying switching duty cycle,
creates broadband noise.

5) All of which are potential sources of trouble in a communications
receiver that wants to find a 0.16 uV/meter signal in the presence of noise.

As a designer of switchers, have you ever had to Qualify a switcher to
MIL-STD-461 and 462?. There is a conducted interference test on the
input power lines to the switcher that is brutal. The ripple on the
output fails the requirement of MIL-STD-462. The radiated emissions have
to be controlled, etc. The switching transients from ALL sources cause
EM Susceptibility in related equipment.

It's not impossible to design switchers for a quiet environment, but
I've spent $millions on getting them quiet enough to meet
MIL-STD-461/462 requirements.

So what would the gain be with that 60" antenna? I see 20-24" or so yagis being sold all over with gains of 12-14dB or so. But from what you're saying maybe these figures aren't accurate either? I guess I'm just wondering whether it is worth it to spend an extra $60 for the 60" yagi rather than the more "standard" 20-24" size... ?

1872. EZNEC v. 4.0 at Dayton

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-07 17:10:19 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <109ngo0dviskpa1@corp.supernews.com>
Source record: 95523

I'll be introducing EZNEC v. 4.0 at the Dayton Hamvention this year, and a new program type, EZNEC+.

Briefly, the main new features of EZNEC v. 4.0 are:

-- Unlimited undo/redo
-- Wire insulation
-- Geometry check (spots wires crossing, overlapping, etc.)
-- Faster calculations (20 to 400% or more, depending on model, machine)
-- Automated loop creation & resizing (for you quad fans)
-- Stack, copy, move, rotate groups of wires
-- 2D trace comparison (put cursor on added trace and see rel. gain)
-- Improved printing (access advanced printer options; default retained)

EZNEC+ has these additional features:

-- 1500 segment capability
-- Circular polarization
-- Double precision calculating engine
-- Direct import of NEC file GW coordinates

New programs will be $89 for EZNEC, $139 for EZNEC+ (web order/download; add $10 for CD, $3 for CD shipping outside U.S. and Canada). A substantial discount will be offered to current EZNEC (and even ELNEC) users. As has been my custom, I'll offer the CD at Dayton for the web download price (a $10 discount).

I'll be located at my usual spot at booth 514, near the Yaesu booth. I'll also have the demo version on mini-CDs to give away while they last.

I hope to have the web site up with the new version at about the same time as the Hamvention (May 14), but don't know if I'll quite make it. Upgrade notices will be mailed out to current EZNEC and ELNEC customers just as soon as I'm sure the web site is working properly. PLEASE DON'T CONTACT ME FOR A CUSTOMER ID. IT WILL BE PRINTED ON YOUR UPGRADE NOTICE. Current EZNEC customers will need the customer ID to get the upgrade discount at the web site.

EZNEC pro versions (EZNEC-M and EZNEC/4) also have the new features, plus they can now do 20,000 segments, and add GH (create helix) "cards" to the types they can read in an NEC-format file.

I'm sorry, I'm really up to my eyeballs getting everything done in time. So I won't respond to any individual questions now about the program. I will, however, try to check back here now and then, and answer questions that are posted.

See you at Dayton!

Roy Lewallen, W7EL

I'm not sure what calcs you need to run, but wouldn't it be trivial to
do a test of Matlab's speed with respect to the sorts of things you
need to do? It's one of the very nice things about an interpreted
matrix language. I use Scilab (freeware), and just ran a little test:
create a=rand(200,200), b=rand(200,200), c=a*b, ainv=inv(a), and then
evaluate ainv*c-b, to make sure it comes out close to zero. It did,
and the whole thing was fast enough that I couldn't time it accurately
till I put it in a loop to repeat ten times. It's about 1.4 seconds
per iteration. Guess I could have let it time itself, too. That's on
a 700MHz Pentium machine. (Considering the work I put into inverting
matrices in my linear algebra class years ago, the speed with which it
can invert a large matrix puts a wry smile on my face.) Scilab, as
Matlab, can compile functions, but if your math is very compact
because of the matrix notation, it may not really matter much; most of
the time is spent doing the matrix math anyway. And if the matrix
notation lets you do things in a way that's more readable, that's a
huge plus, and also consider the time you'll save programming (unless
you already have good matrix libraries available, I suppose).

(By the way, last time I checked, 200*200 = 40000, not 4000. ;-)

Cheers,
Tom

Gene, W4SZ wrote:
"There is no need to invoke phony arguments about waves "shorting"."

Shorting waves does not annihilate them. It merely reflects them. A short is a low-resistance conductor.

A transmission line short is a low-impedance U-turn for for the wave`s current which forces the voltage between conductors to zero. Cancellation of the electric field sends its energy for an instant to the magnetic field. As these two conjoined fields continuously regenerate each other, the electric field is immediately recreated by the enhanced magnetic field. The electric field goes from zero at the short to double the incidet just 1/4-wave back from the short due to addition of the incident and reflected wave vectors (phasors).

For a complete reflection in a short, you need zero resistance. Otherwise, resistance consumes some of the available energy.

When a radio wave strikes the ground, it is reflected. Angle of reflection equals the incidence angle but because the earth is an imperfect reflector the reflection is ncomplete. Reflection depends on incidence amgle, wave polarization, frequency, and type of earth. The reflection occurs as if the R-F wave were an optical wave.

NVIS is simple to do by using a horizontal dipole up 1/4-wave above the earth. The wave is delayed 90-degrees in travel to the earth. It is delayed 180-degrees by earth reflection. Then, another 90-degrees of delay is experienced in the reflected wave`s return to the vicinity of the dipole. The 360-degree total round-trip delay puts the reflected wave back in-phase with newly emerging radiation from the dipole in its travel toward the zenith. If the ionosphere can reflect this high-angle energy, it can cause reception fairly close to the transmitter.

Best regards, Richard Harrison, KB5WZI

A little more explanation about what I posted earlier about a single stub not in general being a very good filter...

Let's say you want to operate on 146MHz and want to get rid of a strong signal from a nearby 156MHz transmitter. So, you think, let's put a stub across the line which is shorted at the far end and is an electrical half-wave on 156MHz. Fine, it'll get rid of the 156MHz signal. -- And that's true enough. But what does it do on 146MHz?? If it's 50 ohm line, it will look like about -j10 ohms at 146! That's not a very friendly thing to drop across the line on our operating frequency. But there's a way around it. If you think of that 180-electrical-degrees on 156 as 180*146/156 = 168.5 degrees on 146, then just add another stub there, also shorted, and 180-168.5 = 11.5 degrees long on 146MHz. That stub cancels out the effect, on 146MHz, of the other stub, so there's essentially no effect at 146, but still the dead short at 156. All this is idealized, for lossless line. In such a case, where the rejection notch is close to the frequency you want to pass, be sure to use low loss line. For example, if the longer stub has 0.1dB loss and the shorter has 0.01dB loss, you'll reflect not a short but about 0.6 ohms on 156, and not an open but about 158 ohms resistive, representing considerable loss. That might be something like RG174 (didn't check the numbers, but ballpark). If you instead use some LMR600 line that has about 1/5 the loss, the resistances will also be in that 5:1 ratio: about 0.12 ohms for the short and a much nicer 780 for the open. Or you can make a really low loss stub (a resonator) from moderately large diameter copper pipe.

Also, you can put trimmer caps across the ends of stubs to make them much easier to tune than by using the "cut and re-solder" method.

If you thrive on just numbers, you can get freeware programs that will calculate all that sort of thing for you, or just do it yourself on a calculator or in a calculating program like Excel or Scilab. I much prefer graphical representations, and use a Smith chart program that does calcs that are just as good but displays the results graphically. I use WinSmith, but there are freeware ones that will do similar things. RFSim99 is just one of several.

Cheers,
Tom

You know, one wonders what happens if you swap the Hustler and the counterpoise? Coax center to a quarter wave piece of wire, shield to a (ugh! I had one once) Hustler not too near the ground. Nothing different probably, but you never know.

I think there are no tests that can be conducted to determine the source of the spurs. RF radiated from antenna could cause interference and non-linearity at spectrum itself. Unless I could 100% shield the spectrum from RF, all tests would be invalid. Even if I stood faraway from spectrum, the spurs could also be observed. However, by transmitting into spectrum using 50 Ohm coaxial cable, no spurs were seen. Possibly because RF was transmitted into spectrum without any leakage which could have large effect in causing interference.

noise.

Potential, yes I suppose.
As I said, I know you can make them perform badly, but it's just not that hard to make them perform well enough that they won't be noticed on your receiver, assuming you don't make it a practice to connect the power supply directly to the antenna inputs.

The receiver itself may create more noise than a properly designed switcher.

> As a designer of switchers, have you ever had to Qualify a switcher to
> MIL-STD-461 and 462?.

That one I haven't. My hamshack dosen't require MIL-STD-461 either. That's a large complicated battery of tests, that by it's very nature is expensive to test to, even if you were testing a D-Cell battery.

I have several switchers in use, all commercial designs, and they are barely detectable on my R-8500 or FT-847. I haven't had to go to any extremes (or even any measures at all) to quiet them.

My PCs are another matter, they have needed ferrites on the cables, and EMI absorption material inside the case, but that has proved to be managable.

1885. vertical dipole array

I used to use something known here in the UK as "Baker's Fluid" . It's a
mixture of zinc and ammonium chloride. The salt and vinegar trick
mentioned below works, but it depends how bad the tarnishing is.

==========

Antenna bandwidth changes very slowly relative to wire diameter. It is best considered in terms of antenna Q at 1/2-wave or 1/4-wave resonance.

Approximately -

Q = 1.7 * [Ln(Lambda / 2 / Diameter) - 1]

where Lambda is free-space wavelength and conductor diameter is in the same units. Ln is the logarithm to the base e.

The formula applies up the point where conductor diameter is about 1/6 of dipole antenna length.

Knowledge of antenna bandwidth is not of great practical use at HF because the Q of the feedline plus tuner has at least the same effect on the overall system bandwidth as the antenna.

Download program DIPCAGE2 from website below to see how bandwidth changes with effective diameter of a dipole cage antenna.

Hmmm, didn't mean to offend, nor to imply that this was the preferred method. However, my entire comment was "Try throwing up on your battery terminals; I think you'll find that your gut contents are more acidic than Coke."

This was an invitation to empirical inquiry, engendered by the original poster's tired old comment about how Coke must really do horrible things in your tummy, since it is also able to act as a metal cleaner.

Hams have no special dispensation to be ignorant about chemistry.

The ARRL Antenna Book has done all the work for us. I put
mine together with aluminum pop-rivets. Got the telescoping
aluminum 6 ft. pieces from Texas Towers who has a wind-
loading PC program to evaluate stress on the elements.

I'm sorry, you lost me there Reg. How does the Q of a modern
broadband amplifier feeding a nom. 75 ohm feedline contribute more to
system Q than an 80 meter 1/2 wave dipole made from 2mm wire -- or for
that matter even one that's a half-meter diameter cage (though by then
it doesn't much matter for ham use)?

Cheers,
Tom

Hello. Anyone have any info or a copy of the instructions on a 15 meter broomstick antenna made by "Antennas by Smithe"? It is a model # 9BR15 approx 5' tall. Thanks, Randy AB9GO. crrandal@earthlink.net

Thanks a lot to Dave Brian and Tom.I wrote out a simple 1D FDTD code with PEC boundary condition , Gaussian excitation in Matlab. (Well , I did not have to worry about multiplying the no. of cells in each dimension to get the total number of cells as Tom pointed out !! I will keep in mind that 200x200 is 40000 and not 4000 :-)). It came out rather nicely. .I guess I will try to develop my code in Matlab and try to port it to C for later versions , if needed.Thanks for your comments and Dave , thanks for suggesting the papers to study.

-Warm regards

Per,

Going from 2 mm to 10 mm wire is not going to make a dramatic increase in bandwidth. If you are trying to cover all of 75/80 meters, for instance, with an SWR less than 2, you are better off having two parallel dipoles. You would have to play with EZNEC to get it right, but you need the dipoles to be resonant at roughly 3800 and 3600.

1900. Elementary question:

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-08 17:34:06 UTC
From: Dave Pitzer <dpitzer@sonic.net>
Message-ID: <iS8nc.10378$Fo4.131170@typhoon.sonic.net>
Source record: 95551

First of all, I'm a novice where taransmitting antennas are concerned.

It seems to me that many AM "broadcast band" antennas are four-footed towers. Do these towers merely serve to hold the actual antenna (a "wire") off the ground vertically. The "wire" runs up the center of the tower?

FM and TV (and some AM) towers tend to be slim "guyed" towers with some sort of antenna element(s) at the top. Is this correct? Is the actual tower ever a radiating element?

Also... Some tower structures (AM, FM & TV) tend to be cited on hight ground -- mountains or atop high buildings. Other antenna structures tend to be intentionally located on "low" flat ground. Why the difference?

Thanks,

Dave Pitzer

Tom, who said anything about 75-ohm lines? And there's still a tuner, with FIXED settings, to contend with.

In any case an antenna can present a match to a line at only one frequency in the band. The transmission line transforms the mismatch at the antenna to something else at the tuner and something yet again at the transmitter.

Lines and tuners have lots of inductive reactance, lots of capacitative reactance, but not a lot of resistance. Which are just as much a part of the system as the antenna, if not the greater part. Q = reactance/resistance. Bandwidth is proportional to 1/Q

What the transmitter sees, even with a precisely known antenna bandwidth, is anybody's guess.

Hi Dave,

No, the physical structure, in this case, is also the radiating
structure. Some are isolated from ground (they sit on glass mounts)
or are grounded and fed by other means.

>FM and TV (and some AM) towers tend to be slim "guyed" towers with some sort
>of antenna element(s) at the top. Is this correct? Is the actual tower ever
>a radiating element?

Depends on the wavelength and the physical dimension and if the
structure is constructed with isolated elements (glass barriers along
its length to become a stacked, phased system). But by-and-large,
those that you see are holding up antennas for the height advantage.

This is not to say that BOTH could not be achieved. Here in Seattle,
we have phased AM towers holding up hundreds of VHF/UHF/SHF antennas.

>Also... Some tower structures (AM, FM & TV) tend to be cited on hight

Those same phased AM towers are in fact atop two of the city's largest
hills, Queen Anne and what we call Pill Hill (lots of hospitals
located there). We also have lots of lake country and estuaries
filled with AM stations. Economics of Real Estate and coverage drives
such things far, far more than engineering.

The tower _IS_ the wire. Some towers have insulators at the base, some
don't, but the metal in the tower is what radiates. The guy wires might be a
part of the radiation system, but usually they're just anchors.

> Also... Some tower structures (AM, FM & TV) tend to be cited on hight
> ground -- mountains or atop high buildings. Other antenna structures tend

> be intentionally located on "low" flat ground. Why the difference?

FM and TV signals use frequencies that travel best in a straight "line of
sight" from the transmitting to the receiving antenna; ergo, they're high up
so that more receiving antenna can "see" them. AM stations benefit from
being near water, and since the frequencies used for AM don't need to be in
a line of sight from transmitter to receiver, they can be low down where the
water is. If a station is using its AM tower to hold an FM antenna, the
location is a compromise between height (for FM) and proximity to water (for
AM).

A 2% efficient radiator and a 2% efficient counterpoise
doesn't add up to 4% total efficiency. :-)

Anyone who wants a portable rotatable dipole on 75m can
do much, much better than two Hustlers. Two SD-20 poles
with high-Q loading coils in the middle of each comes to
mind. And that's not much more trouble than two Hustlers.
The SD-20 approach is available at http://www.wr6w6.com

Hello,

What does "Q" actually stand for as i can't find anyone that can explain
this. I know many people repeat paragraphs of books without understanding
them!
Are you stating "Q" is reactance divided by resistance or "Q" = reactance OR
resistance. You obviously know what you mean but it isn't too clear the way
you're explaining it.

What is "Q" ? So far on this group I have had many answers such as it means
"quality" "goodness" "resitance" etc, but no one can give a similar answer
to anyone else. Does anyone really know or is it a made up term.

> What does "Q" stand for or represent?
==========

Q is a universal measure of the selectivity, the sharpness of tuning, of a tuned circuit at resonance.

It is also the ratio of reactance to loss resistance of a coil or capacitor which forms part of a tuned circuit. Numerically, it is the ratio Q = X ohms / R ohms. It is a measure of the "Quality" of an L or C component.

Values of low Q are 20 or less. Typical values of Q for HF tuning coils are 70 to 400. The physically large coils have the higher Q values. HF capacitors can have Q values as high as several thousands.

In the present context a radio antenna, having distributed inductance and capacitance, behaves as a tuned resonant circuit and has a low value of Q. The loss resistance is the radiation resistance.

A 160 meter dipole of thin wire will have a value of Q around 14.

A 2 meter dipole made of aluminium tubing will have a Q around 5.

The working bandwidth of an antenna can be defined in different ways. But it is always inversely proportional to Q. High selectivity = narrow bandwidth. Low selectivity = broad bandwidth, a desirable property of an antenna.

Correction: some FM broadcast transmit antennas have an input VSWR less than 1.15:1 from 88 to 108 MHz (50 ohm coaxial environment). There IS no significant mismatch at the antenna input requiring the use of a matching network there.

It depends on the application as to what VSWR bandwidth is necessary, but certainly it is not difficult or expensive in many antenna designs to span several hundred kilohertz with a good match to the transmission line.

I did, and in the scenario I proposed, there's a broadband amplifier,
but there IS no tuner (or if there is, it's set to a very low Q
anyway; the Q of an L network to match 75 to 50 ohms is far lower than
that of a single-wire antenna). There's no need for one if the
antenna is sufficiently broadband.

I thank you for the antenna-Q equation. But I disagree that "the Q of
the feedline plus tuner" always, or even very often, contributes more
to limiting the useful (single-setting) bandwidth of a nom. 75 ohm
half-wave dipole driven by a broadband amplifier than does the antenna
itself.

Cheers,
Tom

Hi Dave, (and remember- There are never DUMB QUESTIONS!) The towers you see (even at low elevations) can be used for more than AM broadcast (and ath the frequencies for am, the WHOLE tower is used for the radiator- not the "wire" inside it.
in fact, under OSHA regulations, the "WIRE" you see (and probably associated with a ladder, tho not necessarily, may be "FALL PROTECTION" for those that must climb it to do repairs- what you DONT see is a device that will allow free travel one way (up), but unless a catch is depressed, will not travel down (in case a maintainence worker slips). You may also see smaller antennas (normally towards the top), for fm, 2 way, pageing, and even microwave-- occasionly you will even see metal plates, pich at a 45 degree angle- periscope reflectors for microwave- the dish feeding them sits on the base of the antenna. As stated, for AM, the antenna is USUALLY insulated from ground (the "counterpoise" can consist of wire netting, or individual radials running on top, or just below the surface of the soil surrounding the area.) . When was going to college, worked at a fm station in Portland, Or- that station had something like 8 - F.M stations, and 5 - two way radio stations on a 350 foot tower (Healey Heights) and the tower was probably 30-40 foot at the base! (coax for each of the broadcast antennas was about 8 inches in Diameter!!). Tho because of security problems in todays world, some of the Engineers at these instalations are quite proud to give a Guided Tour- might find it interesting to see just what makes them tick! A 100mhz antenna has several hundred khz bandwidth using #8 wire, but try a
dipole on 1.8 mhz using #8 and you have 10-20 khz.
You are apparently an expert on VHF antennas. I am an Amateur. The antennas
discussed on this group are often 1.8-30 MHZ. HF and VHF antennas are just
alike, but they are different. Got any idea about 1.8 mhz bandwidth?

Counterpoise is required for most antennas to operate "effeciently" (have you ever tried to load a 1/4 wave whip (without one)? Makes great dummy load! Dont radiate worth a darn! Needs the full "1/2 wave" to radiate effectively say that as can be done with loading coils, ect to shorten the effective length, or a ground media for the 1/4 part to work against (tho, at vhf there are SOME 1/2 wave , base coupled antennas that need no counter poise-- but then talking 75 meters- 125 foot tower to do that!!

Oh, and BTW, never stated it would be the "Best" antenna, But, surely would be easier to pack, and set up, then packing a roll of wire , aprox. 67 feet long, and haveing to retrieve it later!! and, would be willing to bet, even as lousey is this is, would beat that one manufactured by a certain outfit that is about 3 foot high, and LOADS up your coax (ISO-T) to avoid lawsuits, like they involved 73 in years ago . Ron-er Jim NN7K

' Corse one can also do similar, with couple coffee cans, and piece of copper pipe soldered to center, coax connectors on sides about 4 inchs from the bottom, same lengths for in and out, and a variable cap at the top to the center copper rod or (older) handbooks show 1/2 wave stripline filter- and these work quite well ! Quite hi "Q" , and hence, quite narrow band passthru. look
in handbooks thru at least 1977-- look in the chapter " Interference with other services"
and btw, yes suckout filters do work-- but, never have been big fan of stubs, rather use resonant cavities-- formula for resonance is Xc= Zo X tan(function of a1/4 wave (90degrees)) . Jim NN7K

Source record: 95469

A 60 inch antenna at 800 megs is about 4.07 wavelengths. Plugging that
into the boomlength to practical gain formula gives 14.2 dBd. A super
tweaked one might give .2 or .3 more, but the bandwidth would be worse.

tom

Make sure to clean that wire off really well after soldering it. All
these suggestions are basically putting acid flux on the wires.

Check out the prices of *some* screwdrivers that are over double the price of mine. I don't doubt you can
get the cheaper antennas and covers. The cheapest one I know of is the DK3 at $150 (last time I checked), and the antenna positioner is over $250. I GIVE away simple
little modules for tuning for 706 rigs that do the same thing
as the fancy "positioners". The only reason I haven't built them for Kenwoods (like TS50) is I can't find the plugs.
Part of the pins are round; part of them are round.

Also, the cheaper ones (usually) are made of PVC. Put
1000 watts AM on PVC and watch your coil become a
slinky toy. Some operators want more than that. Mine are rated at 1000 (recently updated) watts and 1500 watts respectively.

Finally, if your post is meant to insult or worry me, it has not succeeded. My livelihood doesn't depend on making
antennas; I do it for fun and making a bit of change. If I never made another one, it wouldn't hurt me at all. It is a
HOBBY and a way to occupy my time while retired. I have shipped antenna from here to Florida, from here to
Alaska, Texas and all over. It is like anything. I can buy gas at my local station, or I can cross the SC border and
buy it for .15 less. Why do they build Fords and Cadillacs? It ain't all about cost.

And *most* of the makers "skimp" on the covers by using Butyl. I use 1/8" wall Lexan tubes. Butyl WILL eventually crumble. I offer the covers because there is a demand for them. If that "offends" someone, too bad If yours works, that is fine with me--congratulations.

Just in that last week I happened to notice two broadcasting antennas in the vacinity of where I live. In both cases it appears to be two towers about 100'+ tall which are about 100-200' apart. They are in a field with nothing else around except a small building. I see no wire strung between the towers. They are guyed and the guys are broken up with insulators. Are both towers driven or is one a (parsisitic) relflector? Is this generally what AM broadcast antennas look like?

Bill K6TAJ

1924. Understanding Ground.

Newsgroup: rec.radio.amateur.antenna

This might be a question for one or another of the other radio amateur newsgroups, but I figured I kind of already know of some great engineering minds residing in antenna-land, so I would post the question here first.

When I was a kid back in the 50s I built my first novice transmitter with a one tube circuit using a 117N7 which put out a couple of watts on CW through my end fed random wire tuned with a tiny electric bulb and a single loop attached between the two terminals of the bulb.

Oddly enough this circuit only used the hot side of the AC outlet and a cold water pipe ground to the chassis of the transmitter. Our house was built in the early 40s if that tells you anything about how they wired outlets in those days.

I have since dug up a reference to this transmitter circuit in "Ham Radio Projects for Novice and Technician by Bert Simon -W2UUN". Even though this little book came out in 1968 I know that I found the circuit in some earlier publication because I built this thing in 1953. And I am alive to tell the story...eg. not electrocuted. It keyed to the cathode which was also tied to the top grid....kind of like a beam pentode(?). I think I owned one 80m xtal at the time and a Hallicrafters S-53A. [I got distracted from ham radio for 50 years, but I am back....with alot of catching up to do].

My question:
If I were to take a volt (amp) meter and put one probe in the hot side of an AC house outlet and the other probe to a metal rod stuck in the ground out in the middle of a field somewhere (presumably nowhere near a neutral leg), what would my meter read and why?
Deep electro-philosophical answers welcome as long as it is expressed in terms a child could understand. (It seems that this little odd transmitter circuit avoided the neutral leg altogether-- just used the hot side and a ground).

> Bill K6TAJ

Hi Bill,

Ground is referenced at both the generating station and your home in order to complete the circuit. In your home's service mains panel, ground and neutral are bonded together. Before the days of the third wire, added purely for safety in the event of an equipment fault, a faulted piece of equipment still had a return path, just not the added measure we have today of a very short ground path (no pun intended) <G>

With a properly resistive load you could still perform your field exercise, but it would have nothing to do with avoiding a nearby neutral wire which serves the same function anyway. Neutral was always and still is, the return path of a parallel circuit, nothing more or less. It is cold when no load is connected to it and hot (minus the resistance-consumed current of a load applied) when a load is connected.

Further to antenna bandwidth.

The concept of Q = Inductive reactance / loss resistance applies equally to coil plus capacitor tuned circuits and to antennas.

Because capacitance loss is negligible, antenna Q depends only on loss resistance of the wire inductance. Loss resistance = uniformly distributed radiation resistance + wire resistance. Uniformly distributed radiation resistance for a half-wave dipole is exactly twice the centre-fed value, ie., approx 140 ohms.

Formula for the inductance of a straight length of wire can be found in Terman and many other places. It is then a simple matter to calculate dipole Q = inductive reactance / loss resistance.

Bandwidth can be described in terms of the 3dB points or in terms of the SWR = X points.

But, as stated earlier, what matters is radiating system bandwidth, antenna + transmission line + tuner. And doubling antenna wire diameter has no noticeable effect on operating bandwidth. Increasing wire diameter by 100 times may double bandwidth but is not worth the trouble and expense for only one band.

Discussion of antenna bandwidth at HF, always in non-numerical terms, is an overated topic.

Hi Jack,

So could I light up a 100 watt light bulb with one terminal stuck in the earth out in the middle of a field and the other to the hot side of an AC circuit?...I guess so.

The Earth is the ultimate return path I guess. The neutral as I understand it is the center tap of the high voltage step down transformer which takes two hot leads from the high voltage line and steps it down to 240V with a center tap being the "neutral". The neutral is then grounded for extra safety. The neutral (center tap) does not need to be grounded to provide the return path, but what my question is why the Earth per se is also a return path? I guess being such a large mass it is theoretically a zero potential.

Would my theoretical light bulb get brighter as I drove the rod deeper into the earth?

I have seen mention the idea of shorting both ends of the loop and using this as a differnt kind of antenna. Anyone know about this idea. My 540' loop is still in the process of construction. How, why, and for what might I use this alternative rigging? How would I hook it up to the tuner or transmitter and what might it be good for. What would you call a loop shorted this way....I know "shorting" is not exactly the right word here.

Bill,
Just before it blew up, it would light up, yes. Remember I said "With a properly resistive load" and that would be a very dangerous however possible experiment to attempt. The circuit breakers are set to prevent your haphazard determination of what current load is too much - the hot wire supply in should be matched with "cooler" (neutral) return, accounting for acceptable current usage by the load... up to the point where too much current generated heat trips the breaker. Nothing forces you (in your experiment) from keeping all of that available voltage (0v felt on neutral) as long as the current did not exceed 15a or whatever your breaker allows. Obviously a 100w light bulb shorted to ground would blow instantly, before the breaker could protect it..

Assuming a series of (18) 100w bulbs on a 15a circuit (120v), yes the ground rod's resistance (5-15 ohm depending on soil) would allow less than the full brightness of the bulbs, until or if you were able to reduce the impedance by using a larger surface area rod and drive it deeper into wet soil. This is the same principle of making the very best and lowest impedance ground

system you possibly can for lightning protection!

Q is generally taken to "stand for" quality factor. The definition I like to go back to when all else fails is "energy stored divided by energy dissipated per radian." Q really only makes sense when you are talking about single resonators. This definition of Q applies to LC tanks, coaxial cavities, hollow cavities, acoustic resonators, pendulums, or any other singly resonant structure.

High Q resonators "ring" for a long time, a lot of cycles. Low Q resonators dissipate energy rapidly and the ringing fades quickly.

Cheers,
Tom

1.8MHz dipole with 8AWG wire: just use three parallel pieces, spaced
about a foot apart...or make a "bowtie" out of the 8AWG. Or use a
steel cable center core and a cage of cheap 14AWG wires around it.
There ARE cures for narrow bandwidth in wire antennas. Of course, it
may be simpler to just use a matching network ("tuner"), since the
efficiency and pattern of even the simple single thin wire dipole
doesn't depend much of frequency within an HF band.

You have choices here, and I don't much care for generalities that
unnecessarily limit the choices. Just because one person wants to use
a tuner, and retune after any QSY greater than 20kHz doesn't mean
another who wants to use a broadband system should be discouraged from
doing so.

Cheers,
Tom

RE: Tom's comment below -

For an example of the VSWR bandwidth achievable in an >> HF << design, check the antenna described at this link http://www.tcibr.com/PDFs/613tfwebs.pdf. Nominal input VSWR is 2:1 from 2-30MHz . No input tuner is used.

Good VSWR bandwidth in an antenna is not limited to VHF and above.

RF

Visit http://rfry.org for FM broadcast RF system papers.

Bill,
I've 'shorted' an 80 meter loop to load it as a
'sort of' 1/4 wave wire on 160 meters. Disconnected
the 'ground' side of the ladder line and connected
it to the 'hot' side of the tuner (with the 'other'
side of the ladder line). Certainly nothing to brag
about in performance, but it did work. I said a
"sort of" 1/4 wave wire because it's length really
isn't a 1/4 wave long. (Maybe a very 'fat', but 'short'
1/4 wave wire?) Probably didn't work very well because
I don't have any radials in the ground, just a very good
safety ground.
I suspect your 540 foot loop won't load the easiest,
but should make for at least a 'fair' signal on 160 if
you 'shorted' it. But, at 540 feet, you shouldn't need
to 'short' it anyway...
'Doc

Bill,
The voltage on the end of the wire will be something
between 120 vac and 0 vac. Depends on how long the wire
is and the resistance of your 'dirt'. I wouldn't expect
the light bulb to be as bright as it could be (back to the
resistance and length thingys again), but I would expect
it to have some 'glow' to it...
'Doc

PS - Rubber gloves and boots would be 'nice' if you try
that experiment.

Zeno:

I think you are confusing cause and effect. There are many safety considerations in designing an electrical power distribution system. One consideration is this: Suppose some fault occurs which increases the leakage from the primary voltage (anywhere from 4 kV to 54 kV) of your distribution transformer to the secondary which supplies your home, and the secondary is ungrounded. Contrary to the way it would be portrayed on movie and TV programs, your light bulbs would still light normally, and appliances would work correctly (except grounded radios and TVs which actually would blow up) but if you touched anything connected to the secondary service, you would enjoy instant electrocution. So, the reference for the secondary, the center tap of the US 240 VAC system is connected to a ground rod(s) of a specified maximum resistance to earth (which tends to be the potential your body assumes while walking around your house). The design criteria for this fault condition is that the primary fuse will open before the secondary system voltage rises above a safe(?) level. So, neutral is grounded, to a relatively good extent.

Now, to further pursue this mind game, consider the earth to be a copper ball. Then, all of it that is nearby will be at the potential of your electric service neutral. And a sheet metal screw driven into it anywhere within reason would provide an adequate return path for AC drawn from either phase of the service. Real earth is more resistive, depending on soil content and moisture level, so one can approach the copper ball condition, but usually it is more like a bag of loose carbon particles. And, the more surface area of a driven rod exposed to the earth, the lower the resistance and the less voltage drop for a given current, or the more current for a given voltage drop. It seems to all follow Ohm's law, for some unknown reason.

A couple of caveats. One, modern wiring tends to include Ground Fault devices which measure differential current to a wiring device. If more current flows in the hot line then returns there to that neutral, it disconnects the device. So the connection you used would not operate. Two, none of this applies to RF, as in antenna grounds, because reactance must be considered in addition to pure resistance which dominates at 60 Hz. And another: Some to none of this applies in most other countries which use other standards and methods.

> look like?

The usual practice is to drive both towers. Parasitic reflectors don't give sharp nulls, and broadcast stations are usually "protecting" another licensee on the same frequency, so the array will be designed to put a notch in the signal toward the other "priviledged" station, while still assuring the maximum possible coverage in the local area. That means driving both towers.

The guys are broken with insulators in order to prevent the guy wires from becoming parasitic elements, which could weaken the null(s).

This is generally what AM antennas look like if the station in question wasn't licensed a long time back: some "clear channel" stations have non-directional antennas, but that's rare, and some "sundowner" (i.e., daytime-only) stations are non-directional because they have low power and aren't on at night.

The question was the length of a counterpoise, not a rotatable dipole.
I figured another Hustler sure beats running radials out in a portable
situation.

If someone was to ask you how to make their Chevy run better would you
tell him to get a Ford? ;-)

It would read very close to your full line voltage. If you tried to
draw any significant amount of current however, the voltage read by the
meter would drop. The reason is the earth acts like a resistor of some
unknown (but relatively large) value inserted in series with your
circuit. Basic Ohm's law.

Bill,

Assuming that the transformer on the pole supplying the power to your house has a grounded neutral, an "infinitely" high impedance voltmeter will read total applied voltage across an open circuit, and so your meter will read 110/120 volts.

If your voltmeter does not have an infinitely high impedance, the internal impedance of the meter will be in series with the line/meter lead/ground impedance and will read a portion of the applied voltage equal to the voltage drop across it's internal impedance.

Althought we talk about "220 volt" supplies in our houses, we mostly just use 1/2 of the pole transformer for each load, i.e., we connect light bulbs, toasters, and refrigerators between one "hot" lead and a "Neutral" wire _WHICH IS CONNECTED TO GROUND_ as well as to the center tap of the pole transformer secondary. So your meter would read 110 volts, unless it's a very old meter with a very low internal resistance. Something like a Simpson 260, which has an internal resistance of 20,000 ohms/volt, would show the line voltage, because the added resistance of the path from your rod "out in the middle of a field" back to the (grounded) center-tap of the pole transformer would be negligible compared to the meter's internal resistance.

> Deep electro-philosophical answers welcome as long as it is
> expressed in terms a child could understand. (It seems that

> this little odd transmitter circuit avoided the neutral leg
> altogether-- just used the hot side and a ground).

Since the house was wired in the 40's, it probably had metal pipe in it, which means that your transmitter used the pipe as the return part of the circuit instead of the Neutral wire connected to the outlet. It was, and still is, common for your electrician to bond the Neutral to the water pipe at (or close to) the service entry point, and since water meter cases are usually brass, that meant that the connection to your water pipe may have had a lower-impedance path back to the pole transformer than the Neutral wire in the outlet your transmitter was connected to. After all, household plumbing supply pipes are usually 1/2 inch, so you got (assuming good bonding at all the joints) the equivelent of about "four ott", or 0000 gauge wire for your return path.

Connecting a one-tube rig between the hot and ground actually had some advantages for RF: no rf currents flowing in the Neutral, for example, and a little bit of a counterpoise for your antenna. You didn't use "just the hot side and a ground" - you used your plumbing pipes as a substitute for the Neutral conductor, which is always connected to ground anyway. (1)

This might make more sense if I explain some of the history of electrical use in the U.S. The original "Edison" plant produced 110 volts _DC_, and used ground returns extensively, mostly by relying on the metal pipes in the street and in homes. It's for that reason that our "household" current is a nominal 110 volt AC - the RMS, or effective, value of AC required to light an old 110 volt toaster or spin a 110 volt DC motor. (2)

The use of utility pipes as ground return paths between generating stations and homes had predictable consequences, with utility workers getting shocked and injured. Not only that, but it introduced incredibly high "noise" into the ground - not a problem for light bulbs, but a nightmare for the early ground-return telephones - and so the transition to AC was accompanied by extensive efforts to ground all services independently of the utility pipes. You'll notice ground rods at most poles where there's a transformer, and the high-tension wires at the top of utility poles work against a ground which is bonded to the center tap of the transformer secondary, both for safety and to reduce stray currents by distributing ground loads throughout the system (3).

So, long story short, your transmitter was working from hot to ground, just like every other 110 volt device in your home (4).

Bill

(Nother I say is to be considered as competent electrical advice. If you get electrocuted, have your heirs blame Ohm, not me.)

(1) However, this is a good example of how what used to be true is no longer so: plastic pipe is now common, and although I hope a young ham would not consider a plastic pipe to be a "ground", (s)he might assume that an old metal pipe _is_, even though the water feed might have been patched with plastic at some point. Most electrical inspectors now disdain water pipes as

ground electrodes, and require at least one, and sometimes several, ground rods to obtain a low-impedance ground connection for the service equipment in addition to the traditional utility bond.

(2) Edison, who saw his status as Ghod of Electricity eroded by Tesla's more efficient and less costly system, tried to frighten the public away from Alternating Current service by arranging to have condemned criminals electrocuted with AC, thus hoping to demonstrate how dangerous the new technology was. The Wizard of Menlo Park once said that the only way to move electricity from town to town was to charge up batteries and put them on railroad flatcars.

(3) The actual load for the three-phase "high" wires is a Wye connected series of transformers, each (hopefully) distributed and loaded so as to minimize ground currents. On streets with a single high wire, the other two phases are balanced by equivalent runs (using different phases) in nearby streets, unless the load imbalance is negligible. The ground path is a combination of the ground wires strung from pole-to-pole, the pole ground electrodes, the service ground rods at each house, ties to the utility pipes, and the occasional tree limb. The objective is to have a non-fatal voltage between two sides of any severed ground conductor that the public might come into contact with.

(4) If your electrician did his job well, your house's circuits and loads will be arranged so that the net ground current is close to zero, i.e., each 110 volt load on the "black" wire will be "in series" with an equivalent load on the "red" wire, so that the Neutral carries only the difference currents. YMMV.

It's a ballpark estimate and means for every 100 watts going
into the antenna, two watts are radiated. If the feedpoint
impedance is 50 ohms, 98 watts are dissipated as heat in
the antenna, primarily in the coil(s). (Try transmitting 100w
into a 75m hamstick for one minute and then grabbing the coil.)

Maybe so, and I figured a slightly different approach would
triple the radiated power. Anyone who uses a mobile antenna
for portable operation on 75m is simply wasting power since
portable antennas invariably can be longer/higher.

Dear Rob (unknown call; unknown location; no E-mail address):
Your questions are unanswerable.
What constitutes the "best" antenna depends on many factors. You
have only provided the information that you are "up north" and that you
wish an antenna to survive Winter weather.
It is unlikely that someone has "tried" both of the antennas you
mention. If they had gone to that expense it would be to write a
paper/book or because one of the antennas died.
Winter survival depends on a number of factors (including luck).
What is a reasonable design to place at 40 feet in an old, wooded
subdivision is likely to be outrageous at 200 feet in open country.
The ARRL has sold a book on the mechanical design of beams. It is a
good reference to study. The mechanical standard for towers and
antennas is 222F. It too should be consulted.
It will be a few more years before the survival characteristics of
the Step products starts to have statistical significance. I have heard
from riggers that the F12 products do not do well in severe wind/weather
conditions. (You may well not have such severe conditions.)
A search using Google, or the like, will turn up more information.
Be cautious of statements that contend that their antenna survived last
Winter's storm. The writer's location may have shielded the antenna.
I hope that this is of assistance.
Regards, Mac N8TT

Source record: 95501

ok,
I recently built an inverted-v antenna out of 2 lengths of copper pipe.
I centered it at 26.000 Mhz. it seems to have a 3:1 SWR bandwidth of 6 Mhz
(23-29 Mhz). is this typical for this type of antenna?

construction details:
2 lengths of .5 inch copper pipe at 108 inches in length:
4.5 feet of RG-8x coax wrapped in a tight loop (8 turns on 4 2 inch
diameter form as a 1:1 current balun), 100 feet of rg-8x coax to station
(in this case, an FRG-7 SW receiver).

I used an MFJ antenna analyzer to determine the BW of the antenna.

does this look koshur to anyyone here?

So do beer, jams and jellies, and cheeses.

Pphosphoric acid is a week acid, and the pH of Coca Cola is still 2.5.

What's your point?

You're probably thinking of hydrofluoric acid.

Phosphoric acid is a rather common food flavoring agent.

100 feet of coax will make it look a little better than it really is,
but the the bandwidth doesn't sound out of line.

Why don't you download the demo eznec (www.eznec.com) and model it with
various thickness of elements and see what happens?

Source record: 95506

Taking Cecil's example a step further. The radiation resistance [Rr] of
an 8 foot antenna at 3.9 MHz is in the range of 1 to 2 ohms depending
upon coil location. The antenna losses, I^2*R, can be in the range of 10
to 20 ohms [Ra], and the ground losses can be in the range of 10 to 20
ohms {Rg]. So, your nominal '50 ohm load' is comprised of Rr + Ra + Rg = RL.

Efficiency is (Rr/RL)*100%. So, 2/50 = 4% or 1/50 = 2%. Take your pick!

The energy is NOT reflected back. It is wasted as heat in the antenna
and ground losses!

Hi OM,

I was going to point that out, but hit the send button while fumbling
among the keys.

Phosphoric acid is a very good metal brightener. I used it when
cleaning shipboard equipment for Gov. contracts. I recall one fellow
in our group who picked up a coffee cup to use it as a solvent holder,
poured some in, and immediately dissolved the bottom right out. It
was as though he poured it straight through a sleeve.

Everything else being equal, the bandwidth in MHz increases with
frequency. A better indication would be a normalized bandwidth,
in your case 6/26 = 23% which is pretty good. A 75m antenna with
a bandwidth like that would cover the entire 80m band. Of course,
re-scaling would require it to be two pieces of copper pipe 65 feet
long and more than three inches in diameter. :-)

That irrigation pipe comes to mind. Would two 65 foot sections
with a 90 degree angle between them be self-supporting in two
directions? Guy the other two directions?

Interesting responses. This is a great group.

Theoretically, if "neutrals" (eg. the center taps of the step down transformer's secondary) were not grounded anywhere on the Earth, would the Earth still act as the return path?

My intuition says yes simply because of the mass of the Earth. If you have a static charge, for example, it discharges to the ground (or any body of mass) it comes in contact with. So if I had a static charge I can get that current to flow to the Earth or any body of a lower potential. So the "return path" of the Earth, in the strictest theoretical sense does not depend on the "neutrals" being grounded, it is just the fact that the Earth is this large mass at a lower potential. That the "neutrals" are grounded is an additional safety factor. In the era of knob and tube wiring I cannot remember neutrals being grounded the way they are today. There were just two wires going to the outlets. Later it was determined that this was not always safe. This is my simple understanding at the moment, but I am still digesting all the responses here.

remember those funny little straps we attached under our cars supposedly to eliminate those "zaps" from sliding over the car seats? hi hi

It sounds to me like you are talking about audio (or low) frequencies?

I think you are correct in that you need some impedance matching. The
impedance of your antenna is lower than 50 ohms so does not develop as much
voltage.

The best way to work out the impedance of the loop is to measure it. If you
are absolutely sure it is at resonance then it will be purely resistive and
you can measure the impedance of the loop with the equipment you have - if
it is not at resonance there will be phase errors in the following
measurement.

Connect your 50 ohm resister in series with your loop and then connect this
to the output of the amplifier. Measure the voltage across the output of
the amplifier. If it is reading over 100v pk2pk turn the drive down so it
does not saturate the output transistors.

Next disconnect the voltmeter and connect it across the 50 ohm resistor and
note the voltage (Vr). Disconnect the voltmeter and connect it across the
loop and note the voltage (Vl). You know one resistance Rr = 50 ohms.

Since the current is the same in both loads and they are in phase you can use ohms law.

Vr/Rr = Vl/Rl

rearranging you get

R_loop = (E_loop * 50ohms) / E_resistor

it doesn't really matter if you measure RMS or pk2pk

good luck and let us know how you go.

Hi Bill,

"Theoretically" if the neutral has no ground anywhere on the Earth,
then the Hot lead has no potential to anywhere on the Earth. This
theory (being perfect) must of necessity invoke no linkage nor leakage
too.

If you hold a metal cylinder flashlight, how much of the battery
potential is draining through your hand to ground? On OR off? Earth
and the battery still have this vast reservoir of electrons, does that
matter in this case?
>
>My intuition says yes simply because of the mass of the Earth. If you have a
>static charge, for example, it discharges to the ground (or any body of mass)
>it comes in contact with.

The premise of the static charge presumes that the charge was applied
there by reference to another charge (electrons moved from one site to
another). This violates the premise of "not grounded to Earth" as
there must be a complete circuit to perform this act and Earth does,
and always had acted as the reference/reservoir.

Hence your example is mixing two conditions to one argument (the
violation of the original premise).

>So if I had a static charge I can get that current to
>flow to the Earth or any body of a lower potential. So the "return path" of the
>Earth, in the strictest theoretical sense does not depend on the "neutrals"
>being grounded

It never did, the "return path" of the hot lead is always the neutral
lead in whatever form suitable to the current demand. It is a
convention to ground the neutral lead so that the path resistance does
not present one standing at ground potential with a lethal voltage
drop. Earth, in whatever form, is a miserable conductor even if it
presents only one Ohm resistance. That same one Ohm to a 100A service
yields 100V potential at the outlet(s). Ground is ground, and this
guarantees "some" current will seek a path through you if you happen
to hold this blighted, neutral lead. If your path resistance to
ground (much less efficient) offers 10K Ohms (mostly confined to the
dermal layer of dead skin cells, roughly a tenth to a hundredth of

this resistance that beneath this 100ï¿½M barrier); then Ohms law will guarantee a lethal current. But wait! There is an special added bonus!

That same barrier supports a network of ducts for perspiration. Those ducts, under the excitement of an AC current find muscles contracting and relaxing at a 60HZ rate causing them to secrete fluid which in turn lowers the dermal resistance. This is called a positive coefficient wherein more current demands more current. Well, you are already dead, this only serves to cook and baste you.

I am inerested in purchasing one of these anennas. I would like to hear from operators who have used them. Also from those who have assembled them.

I want to know how hard it is to assemble the Titan. How they mounted it (I am looking at pole mount at 10 ft.?) Did you decide to guy it. If so why?

Same kinds of questions for the Sigma 5 or 5-GT.

for both-do they work well enough for DX from the central part of the US to Europ/Japan/Australia etc.

Thanks de ND2E

Source record: 95515

I had a GAP Titan. Easy to assemble, easy to erect, good match most
everywhere except 80m. Performance was poor on all bands compared to a
40m inverted V dipole fed with 450ohm line and tuner and an SGC-230
autotuner with about 35ft of wire in an end fed inverted V shape. I
bought it thinking DX would be better compared to several horizontal
antennas at my location. It seems to defy the laws of propagation, low
horizontal NVIS antennas were noticeably better at extreme distances.
The GAP salesperson at Dayton lied. If you find someone who raves about
one ask what they are comparing it to. If someone simply states it
talked great DX to Europe/Asia from the US, so what. What did they
compare it to??? My opinion is itï¿½s a compromise antenna with
compromised performance and I have tried a LOT of antennas.

Hi Tom,
The thread was "wire thickness versus bandwidth" As you know, to scale an antenna from one frequency to another, you need to scale the wire diameter as well. This will keep the bandwidth pretty much the same.
I thought I was commenting on the bandwidth as one changes the frequency and length of an antenna, but keep the effective wire diameter constant. Of course if you vary the effective diameter, 3 parallel pieces of #8 a foot apart on 1.8 mhz, you change the effective bandwidth.

>you have choices here, and I don't much care for generalities that
>unnecessarily limit the choices.
I did not mean to be general and limit choices, sorry.

You certainly can!!

Total power to the antenna SYSTEM = I^2*(Rr + Ra + Rg).

Total power radiated = I^2*(Rr).

When you divide the two terms to get efficiency the I^2 term cancels.
This leaves Rr/(Rr + Ra + Rg). The current terms drops right out!!

When you scale an antenna's dimensions, including the wire diameter, the *fractional* bandwidth remains the same. So if you scale it for twice the frequency, the bandwidth doubles.

This is assuming that loss is negligible. If loss is appreciable, it becomes a factor in determining the bandwidth. And in order to preserve the loss characteristics when scaling, you've also got to scale the conductivity (as the square root of frequency). This is generally impossible or at best highly impractical, so the bandwidth of a lossy antenna won't scale like it will for a low-loss one.

Antenna bandwidth is usually expressed in terms of the limits of SWR such as 1.5 to 1, or 2.0 to 1.

It can be calculated, or otherwise derived, on the assumption that at some frequency in ONE band the SWR is EXACTLY 1 to 1.

But it never is exactly 1 to 1. The transmission line impedance Zo is never exactly equal to the resistive component of antenna input resistance at resonance. It is usually well away from it. So in practice the actual SWR bandwidth is always broader than the predicted, or stated, or claimed as the best possible value.

Purchasers should be wary of curves provided by antenna manufacturers (or in published articles) purporting to show SWR versus frequency which have a perfect match to the line at some central point along a curve.

Although it should be stated there is much more importance attached to SWR at HF than is warranted by the practical effects of SWR on system peration - particularly in these days of almost universal use of antenna tuners.

Perhaps undue importance arises because the SWR meter is the very last indicating instrument to be found associated with transmitters. It is quite reassuring to see a needle jumping about as one gabbles into the mike.

But will the ubiquitous SWR meter eventually disappear as the automatic tuner becomes the vogue? That will be a sad day.

Incidentally, sorry to be so disappointing, the SWR meter does NOT indicate SWR on the transmission line anyway.

I'm on Spanish red tonight.

Uhhhh, No! The most voltage from either wire of a 117 Volt household circuit to any other wire or
to any made ground is 117 Volts. The light bulb would be quite happy to glow at something up to its
normal brightness for as long as you wanted. Now if the grounded conductor was somewhere out in a
field instead of being the local house ground, then the light bulb would not receive the full 117
Volts, because of the resistance of the intervening earth, and would be unhappily dim.

As for the Original Poster's question about the 117N7 transmitter, they were inherently unsafe
unless built on a chassis insulated from the antenna and ground. The usual method was to use a
floating negative (not connected to the metal chassis) inside the transmitter. The antenna was
isolated from the 117 VAC circuit by the DC blocking capacitor to the pi network. The external
antenna ground connected to the chassis. The cathode of the tube and the negative side of the DC
Power Supply had to be bypassed to the chassis through a large capacitor for an RF ground. In no
case should the neutral conductor be left unconnected, even if a water pipe ground could carry the
neutral current. That would leave 117 VAC on the chassis (and the metal shafts of tuning
capacitors.. and the ON/OFF toggle switch) if the ground wire came loose.

I grew up in that era too and got many shocks from AC-DC radios.

At HF, increasing wire diameter has an absolute negligible effect on antenna bandwidth. Multiply effective conductor diameter by 100 or 1000 and you are getting somewhere on one band only.

But it can be completely spoiled by use of a tuner.

Another point is since the entire tower is RF hot not only must it stand on an insulator at the bottom it also needs a way to get the tower lighting voltage to it. This is done w/ "Austin Rings" basicly a pair of interlocked toroids or rings. In addition, for lightning protection they have "johnny balls" a pair of air spaced balls to form a spark gap.

Do a google search for these and you should find pictures. http://hawkins.pair.com/atcitynj.shtml is one such site, just scroll to near the bottom of the page.

Cecil,
that makes more sense to me now that I think about it.
its a nice antenna too. had a General come by with his 10 meter rig and
test it out. good coverage throughout 10 meters. a little high on the
upper end but still usable. same response on 12 meters too and the HF rig
he had didn't like it much on 15 (needed to use the auto-tuner).

rather surprised this thing works as well as it does considering its
direct fed by coax (though at least a fair number of feet are twined in a
tight-would coil 4 inches south of the feedpoint).

Thanks Ken, you're right. I was thinking that without current-sensing abilities on the neutral side of the circuit that it might allow the full available current, but of course a light bulb would just work as a light bulb, drawing no more power than it was designed for! I feel a little dim myself right now ;-(

Cecil
I thought lecher line measurements used a balanced line.
I'm not smart enough to know how to compensate for any irregulariities
associated with open wire measurements of an unbalanced load. And, it seems
that it would be easy enoughto make a 'good enough' slotted line. But,
since I havent found referance to any home built coaxial slotted lines,
maybe its not as easy as I think.

Hi Reg,

That's good to remember, thanks. When setting up a specific frequency dipole (intending no tuner required for two frequencies, the main dipole and a shorter dipole "fan" under it), the only logical place to test with the bird-meter seemed to be at the transmitter output. Certainly that swr changes as it gets to the radiator, as you say. But once the antenna was trimmed to as near perfect swr as possible, what else would you do? Where else would it be meaningful to measure the swr and best power output, and then make wire length changes accordingly? It seems to work wonderfully as trimmed to 1:1 (best you can read on the tuner anyway) from the tx output. Both the bird and the MFJ-962D and tx meters all seemed to agree they liked that setting.

About the only difficulty in doing it (besides cost) I can think of is it would be hard to find a 5 foot long tube you could cut a slot in and not have it distort due to relieved stress.

Use a square U channel for a bottom and 2 pieces of L to make the top.

Look up the equation for the impedance of square coax, get brass tubing (which comes in increaments of 1/32") for the center conductor, make 2 end plates for connectors, screw the thing together. Probably should use plastic screws for the top so they don't have to be flush on the inside.

Thought about making one myself for grins and giggles, but bought a MFJ analyzer instead; lot more portable.

No Problem. It's a good thing to point out that a light bulb with short leads can be used as a good
test device for the effectiveness of a circuit ground or to identify the hot (ungrounded conductor)
from the neutral (grounded conductor).

Hi Jerry,

It is not all that hard to do in fact. HP solved that problem long
ago by thinking outside of the box by thinking box. As with other
test equipment issues, it is simply a matter of planning and testing
with very simple methods. For those whose greatest physical effort in
Ham radio is sliding a credit card across the showroom display
counter, this is called "work."

Basically you construct your coaxial line with the usual interior
line, but unlike the conventional expectations, you do not try to
emulate the outer portion as a cylinder. You construct the outer
portion as two parallel conductive planes (appropriately shorted to
the connector shells at each end (hence the allusion to box):

view HP 805C Slotted Line picture on ebay at:
http://web.ask.com/redir?bpg=http%3a%2f%2fweb.ask.com%2fweb%3fq%3dHP%2bslotted%2bline%26o%
3d0%26page%3d1&q=HP+slotted+line&u=http%3a%2f%2ftm.wc.ask.com%2fr%3ft%3dan%26s%3da%26uid%3
d218132df118132df1%26sid%3d318132df118132df1%26qid%3d84EF05A9A6090F47B1CEF08664244A1B%26io
%3d1%26sv%3dza5cb0d8f%26o%3d0%26ask%3dHP%2bslotted%2bline%26uip%3d18132df1%26en%3dte%26eo%
3d-100%26pt%3dN4430A%2bRF%2bE-Cal%2bModule%26ac%3d28%26qs%3d0%26pg%3d1%26ep%3d1%26te_par%3
d244%26te_id%3d%26u%3dhttp%3a%2f%2fwww.commentality.com%2fN4430A_RF_E_Cal_Module_5988.html
&s=a&bu=http%3a%2f%2fwww.commentality.com%2fN4430A_RF_E_Cal_Module_5988.html&qte=0&o=0

Where the two planes stand apart, you insert a probe to measure the
potential along the line. The depth of the line within and in between
the two parallel surfaces insures the line isolation (no leakage) as
well as preserving the line characteristic Z.

However, anyway that you look at it (even the lecher line suffers from
this) you run the risk of over coupling and throwing the measurement
into confusion (very simple to make errors). The problem is the probe
will introduce its own SWR and gum up the works if it lacks
sensitivity. I won't bother too much with dimensions here, but
instead offer a formula for such a structure:
Zc = (138/sqrt(e))ï¿½log(4h/piï¿½d)

where
e: dielectric constant (= 1 for air)
d: interior line diameter
h: wall separation

You will want to build it long enough to be more than a wavelength of course.

You will also need to calibrate it to determine the residual SWR it presents to the system (this will reveal construction errors). Off hand, I would suggest that the walls be roughly a 2 to 4 cm apart and at least a 20 cm wide (larger wouldn't hurt).

Build one quick and dirty to get your gross mistakes out of the way without spending too much time on them. I can guarantee no one here could build it right the first time (including yours truly). Once you've got the first pass attempt on the bench, then we can talk about how to use it right. ;-)

Richard

I'm pretty sure I'll try to make it coax instead of "slab" like HP does it. I saw some 2 inch copper pipe at Home Depot today. They sell it in 5 foot lengths for about $22.00. I'm OK with using only 1/2 wavelength for the slotted coax. I thought I might be able to 'get away with' using my scope for detecting the line voltages. I am wide open for learning that my approach has extremely difficult to solve problems. It all seems fairly easy right now.
I was hoping to get a response from someone who either had built a line or knew of a publication on the pitfalls associated with making a slotted line.

Jack, I think you know what you are about. But you may be doing the right things for the wrong reasons.

The ONE and ONLY purpose of the SWR meter is to facilitate the antenna-plus-line (plus tuner if you use one) to be adjusted such that the transmitter is loaded with its design impedance of 50 ohms, plus or minus 20 percent or thereabouts.

What the SWR on the line may be is not relevant. It can be anything you like! It doesn't matter insofar as the adjusting process itself is concerned. And it is not of great consequence anyway.

The meter, Bird or MFJ or otherwise, does NOT indicate SWR on the feedline. This is a popular misconception - a very old Old Wives' tale. It merely indicates whether or not the impedance looking into the transmitter end of the line is 50 ohms or is not 50 ohms. If it is not 50 ohms it won't even tell you what it actually is.

So after adjusting line input impedance to be 50 ohms by some means or other, you may be quite happy to retire under the impression the SWR is a nice 1-to-1 and the antenna input impedance is what you think it is. Whereas it very likely isn't.

But you will have achieved the true objective - the transmitter will be correctly loaded with 50 ohms within plus or minus 20 percent even after taking so-called SWR meter uncertainty into account.

Happy adjusting, Reg, G4FGQ

I HIGHLY doubt it's even possible. UHF is so far from 11 meters in the radio spectrum that aside from scrounging parts, one cannot simply convert a UHF x-cvr to 11 m or vise-versa.

1990. Tektronix oscilloscope

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-10 09:33:59 UTC
From: 4nec2@gmx.net
Message-ID: <ee90361b.0405100133.793350e6@posting.google.com>
Source record: 95441

Hello....,

I know, it's very much off-topic, but as an antenna enthousiast I read this news group a lot, so I thought lets give it a try.

Some time ago I managed to blow-up the input-1 channel of my tektronix 2230 analog/digital oscilloscope. According the Service-manual and compared to the input-2 channel, probably one or more of the following parts are damaged:

Comp-Nr Tek-part-nr Name, description Manufact. Mfr-part-nr

A2Q13 151-1124-00 Trans: JFE, N-chan Siliconix inc. J-2400
A2Q15 151-0711-00 Trans: NPN, Si, TO-92b Tektronix 151-0711-00
A2Q18 151-0711-00 Trans: NPN, Si, TO-92b Tektronix 151-0711-00

A2U10 156-2469-00 Microckt,dgtl: op-amp Texas-Instr. TLC271ACP

Overhere in Europe (except for the TLC271) it seems almost impossible to get these parts. I also tried to contact Tekronix , but without much results.

Anybody with suggestions how to get one or more of these parts ?

Because all components on the (multi-layer?) channel-1 input board are soldered very close together the nicest thing would be if somebody had a replacement channel-1 (or -2) input board (tektronix 2230 or 2235) for sale.....

Or, should I post this message on any other newsgroup. If so, please let me know.

Thanks in advance,
Arie.

Dave,

I didn't come here to fence with you guys. I know nothing about the
relative efficiency of antenna systems.

You could be right and the effiency of a tuned dipole "may" be 2%,
which in my mind means if it were replaced with a regular dipole, the
signal strength at a remote location would increase 50 times, but that
certainly cannot be determined that with that brand of math.

Sorry,

Ron

Yes it can! Gain improvement = 10*Log{50) = +16 dB or about 3 S-units.

Thanks Reg. I only presumed that if my standing wave back at the transmitter was a good balance therefore best output from the antenna was possible. I did think that implies that even considering the somewhat long run to the balun, that reflected power was at a mimimum possible level because a resonant antenna condition (or as close as I was able to estimate) existed. Each time that meter readings were taken was after the whole antenna(s) were raised back up in the air, then lower to trim, raise and measure, etc. Starting with about 10% beyond formula length, it noetheless had to have some material added to one antenna and trimmed from another. From what I have learned from you guys, I attribute this to the varying and unique ground absorbtion variables of my particular installation. The help provided on this list is invaluable. Many thanks.

He's probably convinced that it's possible because he knows most CB sets
have UHF coax connectors.

It may interest some to know that the "UHF" coax connector does not mean Ultra High Frequency. It actually comes from the US Military (and probably NATO) designation: Universal High Frequency Coaxial Connector. In this sense "Universal" means it is found on "practically all" military HF rigs.

Antenna bandwidth (without the use of a "tuner":
A reminder that the BW of an antenna is not always determined by SWR limits. Practical antennas exist where the bandwidth is more reasonably limited by degradation of the antenna's pattern than by degradation of SWR. Antennas also exist where the BW might be specified in terms of limits on efficiency.
The 40 foot high TCI dipole (fat, resistively loaded dipole) might have its BW specified by SWR, pattern, or efficiency.

References?

This sounds more like a retroactive acronym.

NATO didn't even exist when the UHF connector series
was first made.

The UHF connector was designed as a mate for RG-8 coax. It
was found on virtually all radios designed to drive RG-8
during that era. Typical examples of WWII vintage non HF
radios that used UHF connectors were the ARC-1 (120-150MHz),
SCR522(108-150MHz), BC-645 IFF (VHF/UHF) ... much later, the
UHF connector was used on the ARC-27(220-400MHz), URR-13/35(220-
400MHz), all two way base station radios in the 400-500MHz
bands...

I am inclined to go with the "they just didn't know any better"
explanation.

Of course. Also, the BNC connector was originally devised for military applications during the war because existing connectors would rust badly under field conditions. The improved BNC was called that because the Base Never Corrodes.

The SMA connector is just too small to be able to carry any reasonable power level, which is why it got that designation. SMA stands for Stops MicroAmps.

I'd tell you what the designation on the N connector stands for, but it's obscene.

I used to work for Tek many years ago and I'd suggest you not try to substitute parts from other sources unless you are willing to verify the scope performance meets specs afterwards. Tek parts are sometimes selected for a particular performance parameter and making substitutions can degrade performance.

Tek has world wide representatives. Have you contacted your local rep?

It depends on whether you are trying to characterize the antenna or
the antenna system. Characterizing the antenna system is useful
for an individual ham but is not very useful, for instance, for an
antenna manufacturer. Knowing the antenna system parameters and
the individual component specifications allows one to indirectly
calculate the antenna parameters to some degree of accuracy.

Seems to me it is reasonable to quote a 3:1 bandwidth even though
the SWR at the center frequency never goes to 1:1.

Which was along the lines of my post to this a few moons back. He may have
been referring to the UHF Citizen's band - which this conversion may have
then be possible from another UHF range. BUT to take it to 26-27 MHz, I
don't think so!

Lou

2011. Re: 50 ohm - 5 foot long - Slotted line.

Wes

Maybe I missed your point. I am trying to learn how to build a slotted line for impedance measurements at 137 MHz. It would be real helpfull to me to see how someone has built one at home. I'd sure appreciate hearing about how you did it or what you know about how I could build one here in my garage.
In fact, I'd like to know more about why a person (HAM type) would use the slab line configuration in preferance to coaxial.

Jerry

I have been seeing some rather short stubby antennas on newer cars lately. Some of them are short rods about an inch or two long. Others are blades similar to what you sometimes see on large airplanes, an inhc or so tall and 2 or 3 inches long. Of course what I actually see appears to be just the 'radome' covering the actual antenna.

They are way to short to be useable on AM/FM, so my guess is that they are actually:

1. Active antennas for AM/FM

2. The new 'satellite radio' antennas

3. Another conspiracy by the safety nuts who think that car radio antennas are dangerous and have convinced the NTSB that they (the NTSB, that is) are smarter than the rest of us and should tell us what we need.

Any 'experts' out there that know what they are?

If I understand the description you gave properly these antennas are for the XM satellite radio receivers. On semi tractors, look for a whip mounted on a rear view mirror with an inverted cone at the top of the whip that tapers for about 6 inches or so. The wide part of the cone isn't a lot larger than the supporting whip but it is noticeable.

Normally on a hardtop car the antenna is placed near the rear of the roof. If it is a convertible then they will likely mount it on the trunk lid at the back of the vehicle.

Hi Jerry,

In response to this, and your email, your wishes are most likely to evince a deafening silence. If you are trying to survey those who have built one from a population of those who used them, I think you've already hit a saturation of 2 possible users. Your own construction effort would qualify you to expand the population by 50%.

As for why a slab style over a cylinder style. That for me is taken on faith that greater minds, in the person of HP Metrologists, figured that one out a long time ago. Myself, I can infer their rationale that perhaps demands more precision and accuracy than you care to pursue; but as any path demands a handcrafted solution, why put in 80% of the effort for a 20% design when 90% effort would double or triple your return?

Harkening back to my days at Metrology school, I can imagine that the slab method was chosen because of the inevitable inner line sag that would inject residual SWR into the system. Sagging between two plates would seem to me to be a non-issue. Sagging within a cylinder may not bring enough residual SWR to cause you grief either, but you have to build and test one to discover the error of your presumption if it disappoints you.

As for using your scope to eke out the voltage measurements. That is a tantalizing thought, but the big boys accomplish more with less. Simplicity is the keyword, with thinking outside of the box. You are focusing on the literal, absolute voltage measurement when SWR is all a matter of relativity that affords orders of magnitude more sensitivity and resolution (and hence accuracy).

Research the Agilent archives for the Metrology papers of the 1960s. The discussion is very accessible (with only the math necessary to perform a real measurement) and focused to the concept and the theory. The writing of that era is a hallmark of clarity.

On further reflection (no pun), I would retract this because line sag would necessarily induce a voltage variation between the probe and the line that did not actually exist (probe tracking is very important, of course). Sag may not introduce residual SWR, but it may appear to.

Also, yes, you could use a less than one wavelength long slotted line - provided you had a sliding load to make up for the remaining length. In other words, instead of moving the probe to measure the crests/troughs, you move the load (or both very carefully). When you introduce limitations into design and wish to maintain precision, it necessarily follows that you need more standards to compare against.

Richard

I used to think the HP slab configuration was choosen so as to put the probe in a place of minimum fiels within the line. That might be needed so that the probe introduces a minimum disturbance, or influence. The truth is; I dont really know why slab is prefered. I thpought I could attach some light dielectric supports along the bottom of the center conductor to eliminate the serious sag. I think the diam. ratio for the condoctors is close to 2.3 to 1 for 50 ohms without dielectric loading. Thats something I could evaluate after I decide how to make a slotted line.

All thoughts from 'readers' will be appreciated, I'm way out of touch with antenna design these days.

Richard

This is a good example of how out of touch I am. I thought I could get
all the impedance measuring data from a line only slightly over 1/4 wave
long. Even after thinking about it for several minutes, I cant convince
myself that the slotted line has to be more than 1/2 wave long.

I am planning 5 masts for an irregular pentagon to be fed with ladder line to a Johnson Matchbox (275W). The available perimeter is somewhere between <520 - >560++ feet (there is a bit of adjustment available on the exact placement of one of the masts, the other masts are fixed. I want to use this antenna for multi-band use and am not sure yet exactly what precise frequencies I might be on. Since I will hoist up each point with a pulley and dacron rope the excess between the total wire length and the actual perimeter (call it "D") will allow a certain distance away from the metal masts which I assume is desirable. My question is: what would be a good precise antenna length to shoot for given the intended multi-band use AND taking into consideration that I can utilize "D" for spacing the antenna wire away from the metal masts a few feet at each facet?

(1005/3.8)x2 = 529 feet, ok, but is (are) there other length(s) that might have some obscure magical mystery properties I may be overlooking. Obviously I am more interested in 75-80m band than 160m per se.

I though I heard somewhere that calculating for the "lower" part of the 80m band had some advantage, but I cannot fing that reference. Also, once I determine what part of 75-80m to calculate for, do I just double it to be in the ballpark of my available perimeter?

Short Rods are cellphone, in the 2 gig band, or a short loaded 800
celphone. or multibanded.
Blades can be from 49 MHz on up, 800 MHz common.
Many blades are folded over 1/4 wave tuned with a cap at the end, tend to be
narrowband.
Some of the washing requirements for busses, require blade antennas, has to
do with mechanical devices going over the vehicles and harsh chemicals.
Short antennas can be undercover or just business people.
If it is a round dome like a salad bowl on top like on Sears Trucks it is
satellite, Qualcom in L or S band, a data/tracking system (they paid too
much for)

>My question is: what would be a good
>precise antenna length to shoot for given the intended
>multi-band use

Since you are using a tuner, all you need to do is insure the impedance of the antenna system is within the matching range of the tuner at the frequencies of interest. The simplest way is to put the antenna up and then insure that you can tune on the bands you wish to work. If one band presents a problem, then change the feedline length a few feet.
You could model the antenna and do an swr sweep, and that would tell you if there were potential problems, but the tuner is a problem solver as well as changing the line length.
The ARRL Handbook had a list of "feedline lengths to avoid" or something like that when using a 135' dipole for all band use. As far as I know there has never been a list for a 530' loop.
BTW, according to Reg Edwards G4FGQ above 21 MHZ your tuner will start acting funny because of stray inductance and capacitance. I.E. the calculated values if L and C to achieve a match will be off because of strays. I agree with Reg on the many tuners I have built.

> lead...

In other words, if the center tap of the pole transformer is not
connectod to a ground rod, connecting one side of a bulb to ground (to
complete the circuit) can't result in any current (given no other "secret"
paths).

Simply think of the pole transformer as a DC battery. Connect a light bulb
between one terminal of the battery and a ground rod. With the other
terminal of the battery not connected to a groung rod there is no complete
circuit. Its just hanging there.
The pole transformer has the center tap grounded for other safety
considerations - not to conduct current.

Take that bulb out in the field (with ONE hot lead back home) and it
will light with a brightness roughly proportional to the length of its
ground rod...unless there are problems in your neighbor's electrical
systems, then all bets are off...or you accidently grab the wire...

Measure the voltage between yours and your neighbor's ground rods.
Should be interesting.

OT:

Gents.
What you are calling "slab line" is more properly called "Stripline".
It is a very well defined type of transmission line...that is, it has exact equations (unlike the one-sided Micro-strip). I suspect that Jerry's conclusion is right-on. At least theoretically, there is zero field along a line through the center conductor, parallel to the ground planes. So it appears that you would indeed disturb things the least...as long as your 'probe' exited parallel to the ground planes.
Ignore everything but the lower right figure on page 3 of the stripline E field:
http://www.altera.com/literature/wp/lvdsboardwp.pdf

It is all sort of 'sucked' into the ground planes...
The best pix I could find... I think as long as the probe has a small cross section when viewed from the line you will disturb the field the least.
Seems to me in the old days, the probe consisted of a 1N21 diode...

Couple things gang.

The original note was likely a Troll. It wasn't a serious request for information. I don't know the 3MOJ story but there's something odd going on, flame-war, troll baiting, etc.

The use of "UHF" might be a typo, where the intent was "HF".

The other possibility is the freebanders have a different terminology from standard radio talk.

VHF and UHF in freebander, bandit CB lingo isn't 100 mhz, 500 mhz, etc. VHF and UHF are band segments just above 27 mHz and below 30 mHz. .

>When you scale an antenna's dimensions, including the wire diameter,the
fractional bandwidth remains the same. So if you scale it for twice the
frequency, the bandwidth doubles.
Hi Roy,
I have never heard of *fractional* bandwidth. Not unusual that I have never
heard of stuff. If one has a band that is 100khz wide and the 2:1 swr
bandwidth is say 20khz, what is the fractional bandwidth, and the bandwidth?
If you scale the antenna to double the frequency (neglecting losses, or
assuming negligible) and scale the dimensions, what are the 2 bandwidths?
I hope you enjoy Dayton, first time in 5 years I won't be there. It rains
too much when I am up there:-(

(sent last night, didn't show up on my reflector, so,,,)

Thanks Reg. I only presumed that if my standing wave back at the transmitter was a good balance therefore best output from the antenna was possible. I did think that implies that even considering the somewhat long run to the balun, that reflected power was at a mimimum possible level because a resonant antenna condition (or as close as I was able to estimate) existed. Each time that meter readings were taken was after the whole antenna(s) were raised back up in the air, then lower to trim, raise and measure, etc. Starting with about 10% beyond formula length, it noetheless had to have some material added to one antenna and trimmed from another. From what I have learned from you guys, I attribute this to the varying and unique ground absorbtion variables of my particular installation. The help provided on this list is invaluable. Many thanks.

Steve Adam in "Microwave Theory and Applications," pp. 384-385 discusses the H-P slab line slotted section. (No surprise, Adam worked for H-P) He references, "A New Type of Slotted Line Section", Proceedings of the I.R.E., Vol. 38, No. 3 (March 1950).

The slab line as shown is a round center conductor between parallel plates. Equations for this type of line are given in the ITT "Reference Data For Radio Engineers" and are different from those for stripline, which uses a flat center conductor.

General Radio manufactured a true coaxial slotted line section (Discussed in their "Handbook of Coaxial Microwave Measurements"), but it is much more complicated mechanically than the H-P slab line.

As to disturbing the fields with the probe, of course the fields are disturbed. Just like every other electrical measurement I can think of, the device or system under test is *always* disturbed. The question is just a matter of degree.

As far a building a coaxial slotted line long enough for the frequency of interest, let me just ask how would you propose to machine a straight, uniform width slot down the length of a round piece of soft copper. And then, how would you support the center conductor without the supports getting in the way of the moving probe. Answer these questions (to start with) and then you'll understand why H-P used slab line.

Wes

I wonder why such a smart guy like you would ask about how a person would machine a straight slot where a "sraight slot" isnt even needed. Why would you propose use of "soft copper" And, why would you put any supports on the center conductor when it isnt necessary to put them on top, where the probe would.be. Besides, at 137 MHZ, is wouldnt be all that necessary to have the probe moveable continuously. It is aparent to me that either you want to diminish the value of my learning project or you are just not smart. I havent read this antenna news group for very long. Your *help* to me is hopefully not typical. I'm trying to learn. What are you trying to do??

Thanks for the reply. Well the most important factor for me is survival. I live inside a National Park up in Canada where lots of snow, ice, wind, etc occur during the long winter months. The antenna will be located up in the clear. There will be not much around to shield it from the winds.

The SteppIR products looks interesting but they do not have much of a track record. I used to use a Cushcraft R7000 but that only lasted 3 winters. I

am not that impressed with the strength of Cushcraft products.

Rob

Though you don't usually see it for sale, "coax" can be square as well
as round.

Why build a square line? Because it is a hell of a lot easier to mount
and hold on to while you are doing the metal work and easier to build
a centering probe carriage on a flat surface.

If I understand correctly: Q = "Quality factor" of a tuned circuit, a measure of the energy stored in the circuit ato the energy dissipated or lost. Quantitatively it is: Reactance/Resistance and is a unitless ratio. A "High Q" circuit is one w/ low resistance, the ideal case being an LC circuit with the DC resistance approaching zero hence Q approaching infinity. In practical terms it is a measure of the lossiness or damping in the circuit. Note that for pracical purposes a high Q may or may not be a good thing.

If you don't think the longitudinal slot needs to be straight down the
length of the line then let's stop here.

If I can convince you that it needs to be then we can proceed.

|Why would
|you propose (the) use of "soft copper"(?)

Perhaps I shouldn't have said "soft" copper; nevertheless, copper
isn't the easiest material to machine, and it was you, you should
recall, that mentioned the use of copper water pipe. If you have a
milling machine with five or six feet of table travel, then good for
you, have at it.

|And, why would you put any supports on the
|center conductor when it isnt (sic) necessary to put them on top, where the probe
|would.be.(?)

The center conductor needs to be precisely located so as to not have
the probe coupling vary as it is moved. This will necessitate a fair
number of disks/beads or whatever. To be precise, the center
conductor diameter should be reduced (or the outer conductor
increased) wherever there is a dielectric support. If you intend to
slot the supports, then the missing dielectric will modify the
effective dielectric constant. Be sure and calculate that effect.

|Besides, at 137 MHZ, is wouldnt be all that necessary to have
|the probe moveable continuously.

Oh, I didn't know that. Apparently General Radio didn't either; they
had a micrometer attached to theirs to measure position to the

Unfortunately, no, unless you want to use command line nec code.

But then again, if you're really a Unix man, you have a 64 bit Sparc machine into which you can pop a SUNPCI card for that occasional treasure (like eznec) that requires self debasement. Run windows in workspace four and switch back to workspace one if you hear someone approaching.

Well Wes I see it *IS* time to stop this rant. You *are* much more
educated than I am. And I see you as also being smug and negative , at
least as your help applies to my post. Why would I care if the slot was
straight?? That makes no sense to me. I certainly have no reason to
dissuade anyone from making the slot straight. But, why? If you are so
smart, perhaps you can tell me _why_ something is done rather than just
stating "thats the way HP or General Radio did it". What am I missing
here?? I think that it would be nice to have the slot straight, I had
intended to do that a VERY simple way, on a garage sized Bridgeport. Have
you no concept of how to ,machine metal?? I wonder why you even bothered to
post to my question when you make wrong statements.
Please dont go away till you tell why the slot in a line must be straight
if the line is to be used for impedance measurement.
Yeah, Wes, There is an amateur radio group thats interested in monitoring
weather satellites. Does that bother you?? What advice did Richard give
that might help me build a slotted line??
Please take a few minutes to consider the validity of your advice before
offering it. You seem to get side tracked easily like the softness of
copper and the length of what a mill can slot. Try to focus on the fact
that Jerry is trying to learn how to build a slotted line at home. If you

have *ANY* helpfull information I will certainly appreciate hearing it.

Jerry

Source record: 95395

Jack, I got your message first time.

Juggling with antenna height, lengths and angles, perhaps even varying line length, does indeed eventually obtain a 50-ohm load for the transmitter. But the ONLY way of finding what the antenna impedance actually is is to get up there and measure it in situ - out of idle curiosity. ;o)

Incidentally, the forward power indicated by the Bird is correct regardless of SWR on the line simply because the impedance looking into the line is near enough to 50 ohms. In this respect the meter behaves as intended.

And practically all of the power entering the line will eventually be radiated because, although the SWR is not known, by virtue of the near-to-resonance antenna(s) it cannot possibly be high enough to worry about.

Fascinating subject! I've always been hooked on it. There's something about transmission lines. Yet, believe it or not, I've never used a Smith Chart in 60 years. Too unecessarily complicated.

Fractional bandwidth is bandwidth in Hz divided by
the center frequency in Hz. Multiplying by 100 gives
a percentage bandwidth. Both are normalized bandwidth.

A slotted line is a fundamental Standard of Impedance. It relates impedance measurements to the absolute standard of length, the International Metre!

Its weakest feature is the probe mechanism itself. Its electrical presence is unpredictable. Incalculable. Uncertainty can only be minimised.

Or am I 60 years out of date?

Does anyone know what is the uncertainty in measuring an impedance of, say, around 100 ohms at 10 MHz, as may be claimed by a National Measurement Standards Laboratory.

What may be claimed by an instrument manufacturer in the sales blurb is another matter.

Reg

I would sure like to get some information from you. I think you are the kind of guy who would know about how this line might be made to work. I have some 'notions' that may well be wrong, and I'm too easily confused to work this out alone. It seems to me that a "home made" slotted line wouldnt have to be 50 ohms, yet it could accurately measure load impedances.
For my purpose, I'd want to try to get the line impedance as close to 50 as practical. But, if the slotted line's impedance was 48 ohms or 52 ohms, the line would give quite good information on load impedance. That would require alot of testing to actually determine the Zo of the line. But, I would like only to get real close. I dont need a lab standard.
Since I've gotten so involved with this news group discussion, I'll start building a slotted line useing that 5 foot long piece of copper tube at Home Depot. Still, it would be more satisfying to know more about what I'm attempting. It occurred to me that, if building a slotted line for impedance measurement at 137 MHz was easy, someone would have done it already. So, I'm not real confidant that I'll be successful.
I'd thought I might be able to use my Oscilloscope with a sensitive probe for the "voltage measurement". But, since I'm hearing nothing from this group about how slotted lines are home made for VHF impedance measurement, I'm not confidant I'll be successful.

Of course it is not you who is out of date. It is me. I've been away from electronics and antennas for the last 35 years.

Jerry

I remember making some measurements on half-inch 75 ohm coax at
Texas A&M by simply pushing the braid away from a place on the
inner insulation and drilling a small hole to the center conductor.
We used an RF VTVM probe. I remember seeing the effects of
standing voltage waves but I have no idea what the accuracy
was.

2051. Re: Optimizing for Loop Length

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-11 08:17:41 UTC
From: 'Doc <w5lz@cwis.net>
Message-ID: <40A08C25.F8521ADA@cwis.net>
Source record: 95402

Bill,
Unfortunately there are no 'magic' lengths for your loop. Something in the neighborhood of 520 feet should work well on 160 meters, 250 - 260 feet for 80 meters. The limiting factor is the 'MatchBox', it doesn't have the impedance tuning range other tuners have because of the small number of inductance taps it uses. (It's 'big brother' has the same limitations, by the way.) The 'MatchBox' being a real 'balanced' tuner is nice, but just not that big'a deal for all practical purposes.
In general (meaning that there are always exceptions) the largest loop you can get into the air is the way to go, if you cn 'match' it...
'Doc

2052. Dipole keeps melting?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-11 08:38:06 UTC
From: Andy <andrew.birch@nospam.bluewin.ch>
Message-ID: <40a090ee$1_2@news.bluewin.ch>
Source record: 95403

Dipole keeps melting?

I've got a multi-band inverted V trap dipole antenna which as my first HF antenna seems to working fine, I like the fact that can get away without a tuner on most bands.

However I've just started getting into 80meters and the tip of the dipole keeps melting the guy rope isolator hence the dipole leg falls to the ground, only running 200watts, the antenna is rated for 1kw.

Everyone suggested its high SWR but not according to 3 different SWR meters (1.1:5) I always use a tuner built into the amp to give the perfect VSWR but after 10 seconds the melting starts and the VSWR starts to increase..

Any ideas?

2053. Re: Wire thicknes versus bandwith

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-11 08:46:47 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10a14noilnhvm91@corp.supernews.com>
Source record: 95404

By fractional bandwidth, I mean the fraction of the operating frequency that the bandwidth is; or in other words the ratio of the bandwidth to the operating frequency. For example, if the operating frequency is 10 MHz and the bandwidth is 1 MHz, the fractional bandwidth is 0.1 (1 MHz / 10 MHz). If you scale the antenna to 20 MHz, the bandwidth of the scaled antenna is 2 MHz. The fractional bandwidth is 2 MHz / 20 MHz = 0.1, the same as before it was scaled.

I don't have enough information to answer your question, since you didn't give the operating frequency. I hope the example I gave will clarify what I meant.

I always enjoy Dayton. It's a pleasure to meet EZNEC users, potential EZNEC users, and some of the many people who read this newsgroup. And if rain bothered me, I sho' 'nuff wouldn't live here in Oregon!

Hello all,

The last days I was searching for more info o how to build fratal antennas on the web. But besides lots of links to fractenna.com and a few powerpoint slides I found nothing.

Has anyone sucessfully build such an antenna for HF? Is anyone using it?

Kind regards,

Jan, ON5DOA

==========

Fractal antennas at HF stay up long enough to discover they don't work any
better than multi-band dipoles. Or simple verticals.

The radiation patterns, of course, are somewhat modified but not enough to
make any practical difference. Particularly as they are not rotatable.
What's the point in having a rotable antenna which from one band to another
is omni-directional?

Efficiency-wise you can't improve on 95 to 98 percent anyway.

All this can be deduced just by looking at them. Like conventional antennas
they are just a few wires in space at various angles. How can an additional
bend in a wire have a significant effect?

But as you are a confirmed experimenter I guess I am unable to discourage
you from your next project. I'm sorry I do not have any antenna wire
dimensions readily at hand.

As for me, in my time I have had experience with a variety of dogs-hind-leg
fractals without being aware of it. Is an inverted-L a first-order fractal?

Radiation patterns are not as omnidirectional using this method as they are when a tower is series-fed. The FCC frowns on them, especially for use in directional arrays. The following link may be of interest:

You are using a rope that absorbs RF energy and has a low temperature melting point. There is a very high voltage electric field at the end of a dipole which gets absorbed by the rope causing it to melt.

Spend more money on better quality rope. Stay away from 'poly' (or polystyrene rope). Nylon is good (but stretches). Dacron is considered better. Natural fiber ropes are very good (such as hemp). In general, if it doesn't cleary identify what type of plastic it is, don't buy it.

I don't think an insulator would make much difference for this problem but you should be using one anyway.

Makes BIG difference. You have high RF volatge point at the ends, you need good quality insulator that doesn't absorb water (like rope) or melt under RF. It helps to make small loop of wire, so it is terminated in "capacitor" plate rather than sharp wire end (had that problem with balloon vertical).
Situation gets worse in salty air environment, where rope becomes conductive when soaked with moisture and salt. Loop made of plastic ties works OK as insulator, rope tied directly to the end of wire is a NO-NO!

What happens at the tips of the dipole has virtually nothing to do with the SWR at the transmitter. The voltage at the ends of the dipole for 200w will be in the ballpark of 600 volts RMS, 1600 volts peak-to-peak.

What are your insulators made of? Change to glass and the problem will probably go away. If you are in a salty environment near an ocean, that will aggravate the problem. Sounds to me that you simply need better quality insulators.

Check the websites of places like RF Davis, The Wireman or Radio
Works. They sell rope that is appropos to antenna use -- it stands up
to the outdoor environment, and doesn't stretch too much. They also
sell end insulators for antennas -- sounds like you may not be using
any -- the wire shouldn't tie directly to the rope.

OK, I get your point. If you've already have a complete set of antennas, it
will probably be no use of building such a new one.
From my point of view, fractal antennas seem to be MUCH smaller than the
full size ones. So it would be an ideal solution if you live on an
appartment or don't have the permission to place a full-sized antenna
somewhere.

So for me, it would just be a better solution than 2 times 5m of wire with a
balun in the middle.

You're hitting a current node out at the ends of the wire. You could add some wire to the 80M elements, but if the antenna is working properly, your better option would be to find better end insulators. Ceramic dog-bone insulators are only a couple of bucks apiece...

Reg, G4FGQ, dismisses fractal antennas as not improving on the efficiency of radiation, but that may not be the intent.

Kraus, in "Antennas" says:
"They also provide new insights into antenna and array design----.
----Interestingly, the self-repeating different-size structure of a log-periodic antenna qualifies it as a fractal form."

I will try something like this to measure the impedance of the loop+cap.
But my problem for the impedance matching is that I don't know the amplifier
output impedance.
It's a basic class-E amplifier (A self + an IRL510 MOSFET)
Is there a simple way to measure it or to compute it ?

Thanks,

Marc

One advantage of slab line is that when you drop something like a set screw into the line, it falls right on through. (Been there, done that).

I've used the HP slab-line instrument and obtained very good, repeatable results with it.

Others have commented that the big advantage is ease of fabrication, and I have to agree. Cutting a slot in a water pipe seems like a lot of trouble for minimum gain.

Another alternative might be a trough line. This is a slab line with bottom side closed off. The advantage this would provide is a means of supporting the center conductor by means of a longitudinal, dielectric strip between it and the bottom plate of the line. A long piece of Teflon fiberglass would be ideal for this. The line dimensions would have to be adjusted to maintain a 50-ohm Zo.

Anyway, it's an interesting project. Good luck with it.

http://www.rdrop.com/users/billmc/phone_antenna is built around
a ".01uF capacitor", but what kind? Are big .01uF capacitors better
than small ones etc.?

Is .01uF critical or is there actually a range that is acceptable?

Also the "RF connector" isn't clear. What are examples of this "radio
frequency connector"? Perhaps just coax to alligator clip?

Is the 50 ohm coax critical? How about a plain wire from the capacitor
to the radio's telescoping antenna? Should the telescoping antenna
still be extended, or retracted?

How do we know if our phone line antenna is working properly? Should
time signals on 5000, 10000 khz etc. jump out in perfect clarity?

Certainly there must be a slight advantage between one of red and
green vs. the other... or might we not even bother comparing, as they
are certain to be the same?

By the way, I found a .01uF capacitor that the capacitor numbers web pages
don't seem to decode: 103K PE50. I can't figure out what the PE50 or
PE5Q means.

Lastly, the article has some spelling mistakes, e.g., lightening arrestors.

Seems like the postings I've seen here are off on the wrong foot.
Yep, there will be problems, but I've learned a lot more by building
and experimenting with things that didn't work, than listening to or
arguing with people telling me that they won't work. And in fact, a
lot of the time they DO work well enough for me to accomplish what I
wanted.

So I'd like to encourage Jerry to have a go at the copper-pipe slotted
line, keeping in mind the pitfalls that have been mentioned and
thinking of ways around them. I know I would have no trouble at all
making a uniform narrow slot in such a pipe, maintaining a radial
angle straightness well under a degree, without using a milling
machine. I know I'd have no trouble supporting the 7/8" diameter
center conductor to maintain the impedance within a fraction of a
percent over the line length. With proper geometry, sag would not be
an issue for coupling. (Keeping the line vertical is one way, but not
the only way.) Perhaps more important is the initial straightness of
the pipes. 3/4"nom pipe is stiff enough that I can see doing this
with support only at the ends, so impedance AND velocity factor
variation caused by dielectric supports are no longer issues.

Will everything go smoothly? Heck no! Will Jerry learn from doing
it? You bet! Go for it, Jerry, and please see if you can write up
something about your results, to share with others. Listen to the
advice you get, but make up your own mind about what will work best
for you. You should be able to make very decent estimates of the
effects from the problem areas folk have mentioned, through either
formulas or measurements or both. You should be able to make tests on
your line to see if it's performing like you think it is, by applying
known loads and testing at various frequencies, using assorted
detectors and probes.

Cheers,
Tom

I don't have one but I have heard several with both the 3 and 4 el versions.
One, K7SS, has the 4 el with the two extra 6 meter elements. He was loud on
6 and I am all the way across the continent from him.

W1NA has stacked the beams There are now several others...

Sounds like a winner to me especially if you want one antenna for 20 to 10
plus 6.

in a never ending quest to acquire antenna knowledge
i've been doing some reading of a paper back book
by a well know antenna guru who's now a sk.
he claims that if a vertical antenna is fed at it's base
with a parallel resonant l/c circuit and tapped on the
inductor to to get an appropriate swr match, it's
rf ground can be no more than a 3'x3' screen combined
with a rod in the ground.

in my mind, this seems to be something for nothing. if true
why do i read about the importance of having a number
of radials?

questions, comments, pronouncements from the gurus on high

Two words - coil loss. A center-fed 1/2WL vertical would
probably be better - no coil.

Source record: 95334
Cross-posted to: rec.radio.amateur.antenna,rec.radio.shortwave

Remember lightning can induce some large voltages on the phone lines too.
(got a receiver smoked in the 70's by using a "very ,very long wire" like
antenna.
Most have 70 volt ringer voltage, some with much higher voltage spikes,
rating on cap should be high, .01 at 200 volt big is usually a sign of
higher voltage rating. Ceramic. and voltage limiter of some sort, 50/100
volt (sounds like a neon bulb!) on the other side of the cap (not telco
side)
Good idea is a preamp, but you needs good FM TV signal killer filter in
front.
0.1 may be too big, lets in too much noise from power lines.
The line may look like a high impedance, 1000 ohms or more, but the preamp
is your "matching" device.
Don't let the phone people find out, they control the government.

Double check the antenna details. I suspect you are describing the
matching circuit for a 1/2 or 5/8 antenna, not a 1/4 wave antenna.

I shall give it a try and see what happens. Is what you mention
the reason some homebrewers build there own matching networks?
Man, in the old days I remember there were a lot of those large
var. caps. in the ham shacks, but not anymore.

Palstar has a nice unit, but we are talking much bigger
investment. Basically, I am just putting up the antennas which
I can get away with given the boundry conditions at the qth.
Whatever I get, I am sure will be interesting. At this point, I
can, at various points here put up the loop, and up on the hill
in another "shack" I can probably fit in a double extended Zepp
(again with the ladder line). If I can get my archery chops
perfected there is still the possibility of a 160M OCF into a
tall Eucalytus tree and spanning to a mast on the side of
another chicken house. Each antenna situation, will be like an
expedition to another little shack on the property, could be
fun.

>Jan, ON5DOA

Hi Jan,

The reason you see such a void of examples is because of your very
question:
who has built one?

This question above is the one that follows:
which one to build?

And this question above is the one that follows:
what limitations do I have?
or:
what qualities do I want?

Your question is raised here on sporadic occasions, and the poster
NEVER returns to report a successful outcome. This is not due to lack
of information. For such (the largest compilation in the world)
visit:
http://www.qsl.net/kb7qhc/antenna/fractal/index.htm

You should immediately notice that the first impediment is found in
the very nature of fractal shapes.

Do you want gain? Seems not, you do not describe having a large
enough space to do that.

Do you want multi banded resonances in a small space? Probably, but
you will find very, very few examples worth the effort (frankly none).
In all likelihood you would need a tuner, and if you had a tuner, you
should skip the complication of this academic trash.

In open competition between an Amateur and the professional fractal builder, the professional lost against 6 designs that trounced the best professional fractal on the basis of gain for the smallest footprint. That is to say, all seven antennas were bound within a prescribed "small" area (such as you describe), and the fractal came in dead last.

>
>Marc

Hi Marc,

For actual specifics of your device, go to:
http://www.irf.com/product-info/datasheets/data/irl510.pdf
The answer to your literal question requires more details of the
circuit, as the device shows a drain-source resistance that is common
of many finals transistors found in 100W amateur transmitters which
typically exhibit a 50 Ohm source Z at rated power.

This exhibited characteristic Z is a consequence of Z multiplication
through conventional transformer theory. These designs also have the
benefit of low pass filters aiding a smooth transition of Z from the
device Z on the order of 0.5 to 1 Ohm to the System Z of 50 Ohms.

If your amplifier lacks in these regards, it will suffer in efficiency
in spite of the claims of designs of its class. You may wish to
consider driving a small antenna directly to aid in matching. This is
because very small antennas (once the reactances are balanced out, an
important consideration) exhibit a much smaller load resistance that
corresponds to your device's natural output Z. However, to maintain
efficiency, you will need to be scrupulous about all Ohmic sources of
loss that come from construction issues.

The impedance would be +j50 ohms, that is, 50 ohms of inductive
reactance. If you open the far end, you'll see -j50 ohms, that is, 50
ohms of capacitive reactance, at the input.

> I would sure like to get some information from you.

You don't sound like the CIA so I'll do my best.

You are correct. A home-made slotted line can be any value Zo provided you know what it is. But it is prudent to be close to the standard 50 or 75 ohms because of the Zo of any other cables and connectors to be used in conjunction with it. Otherwise you will forever be calculating corrections for impedance mismatches.

And how do you know what Zo is? You CALCULATE it from measured dimensions of the line's cross-section. After all, that's why you constructed it in the first place. Uncertainty in Zo depends on cross-section measuring accuracy and, of course, on the accuracy of the calculating formula.

The most simple cross-section is circular coaxial for which Zo = 60*Ln(D/d) exactly. But there's difficulty in producing a narrow slot without mechanical distortion. If you can think of a way of doing it that's fine. It depends on what measuring accuracy is required. Fortunately, Zo is relatively insensitive to absolute measurements on the cross section. Quite a big fat, strong, easily-measured line can be made.

Note that absolute measurements of the cross-section are not required - only the RATIO D/d is needed. This freedom also applies to all other shapes of cross section. There is no requirement for a length of line to be absolutely straight unless you intend to make an international measurement standard out of it. ;o)

The next most simple cross section is a square or rectangular aluminium trough or channel with the open top capped with 2 parallel straight strips spaced apart by the width of the slot which should be no wider than absolutely necessary. The separate parts can be screwed together.

A problem is providing support for the inner conductor of a long length of line. Ideally it should be rigid enough to be self-supporting without significant sag. Hard aluminium (Duralumin) alloy will be OK. A single support, half-way along the line, could be made from a THIN rigid plastic plate about an inch long.

A square or rectanglar cross section will allow the probe carraige to slide smoothly along the line. The formula for calculating line Zo will be fairly simple. I'm sure it will be available from some reliable source. Just don't even dream of deriving a formula from first principles. Accuracy of determination of Zo should be within a few percent even using a wooden ruler.

Departure of the inner conductor itself from a circular cross section, eg., square or moderately rectangular, will not detract from measurement accuracy for the degree of accuracy you say you require.

Below 200 or 300 MHz there's no need to be very particular about the coaxial connectors at the ends of the line. You should be more concerned about uncertainty of the impedance of the coaxial cables used in conjunction with it.

Can't think of anything else at present.

How do you propose to use a slotted line to measure unknown impedances?

Reg, G4FGQ

For lossless coax, it would be purely reactive, close to +jZ0. Questions
like that are easy when one understands the Smith Chart.

Roy,

Many years ago an article was published showing nomographs for using 1/8
wave lines for universal impedance matching. Do you recall where and when
that appeared, by any remote chance? I know you can do all this with
computer programs now, but I can't easily carry a computer or software into
many of the places I go.

2101. Re: shorted 1/8 wave transmission line

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-12 03:55:56 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <c7s78cfpj1@titan.btinternet.com>
Source record: 95351

The input reactance of a shorted length of line is given by -

Inductive Xin = j * Zo * Tangent(Theta)

where Theta is line length in degrees.

For a 1/8-wavelength line Theta = 360/8 = 45 degrees, Tangent(45) = 1.0,
and for Zo = 50 ohms the input inductive reactance is also 50 ohms.

==========

For an open circuit length of line -

Capacitative Xin = -j * Zo / Tangent(Theta)

So for open-circuit 1/8-wavelength line and Zo = 50 ohms, input reactance is
a capacitative -j50 ohms.

The resistive component of input impedance is very small because line loss
is very small for 1/8 wavelength.

Reg, G4FGQ

Amateur radio transmitters do NOT typically exhibit a source Z of 50 ohms at rated power or any other power.

A conjugate match does NOT exist. It cannot play any part in transmitter design.

Actual source Z, whatever its value, appears purely by chance AFTER the design has been completed.

Even the designer doesn't know what value it might turn out to be. And the amateur radio transmitter user couldn't care two hoots what it is.

I thought this had all been settled a few years back. But no! It seems the Old Wives are still plagiarising each other.

Reg

We (myself and other classmates) did an entire numerical electromagnetics class in Matlab. It's true that Matlab 'for' loops are slow... usually the execution time of the programs was completely dominated by actually 'filling up' the matrix (or cells) rather than, say, inverting the matrix, updating cells, etc. Even so, for a 200x200 FDTD program on any contemporary PC (>1GHz), Matlab is plenty fast and I'd argue the ease of plotting/manipulating the results more than outsweighs the generally ignoranble speed penalty.

Heck, I did a FDTD program in C back in 1994 on some PA-RISC HPUX workstation, and I'm _sure_ Matlab is a lot faster on a modern PC than C was back then, and back then it was certainly fast enough!

BTW, look into parallelizing your code... sometimes it's a lot more trouble than it's worth, but often it's very easy to get Matlab to fill in the results of an entire row or an entire matrix in a single statement if you code it correctly.

Reg, let me guess: you dug that Smith Chart out after all huh? he he he

Btw I had a Power Quality engineer that I was discussing ground line impedances with remind me that the same 1/4 wave phenomenon can happen in runs of ground and bonding too. The same radial or parallel or "web" of connections alleviates that risk with lightning grounding as it does with RF grounding.

Jack

They are even easier WITHOUT the unessessary over-complication of the chart.

A student's valuable time is much better spent learning about transmissiom
lines instead of how to use an antique chart. The answer can be worked out
in the head in less than a second. Tan(45) = 1.0000000 and therefore X =
Zo.

Sorry to hear about your pH problem. Isn't there an ant-acid preparation
available in this modern day and age?

It thus follows there must be SOME Z exhibited, any value of which
occurs by happenstance and whose effect, easily determined, is a
probabilistic spin of the chambers in a capitalistic russian roulette
in the market place. Imagine trying to sell your rigs with this wild
inconsistency in quality and performance. 80% of your product would
be RMA'd to oblivion and your production line brought to its knees
with the loading docks running in reverse. Talk about a mismatch in
THAT line - I love it! We have a description of a conceptual death
wish embraced with a vengeance.
>
>Even the designer doesn't know what value it might turn out to be. And the

Already some time ago I experienced the same thing, as I did not want
to use ceramic or glass insulators which would make my antenna
system(s) even more visible.

Now I am always using transparent 'Bic' ball-points for which I have
removed the the 'ink-cartridge'. Using this tranperent enclosure, on
both sides (using the small nail and the soldering iron) I melt 2
holes. At one I connect the antenna wire and at the other I connect
the guy rope. After using this solution I did not have these problems
any more, even using considerable power.

I do not know if these 'Bic' ball-points are available in the US, but
overhere in Europe they are widely used.
For an example picture I found the below url on the Internet:
"http://www.findaproperty.com/cgi-bin/story.pl?storyid=5985%20-%2015k"

Arie.

p.s. I almost forgot: All this has nothing to do with SWR

Hi Richard,

En Richard Clark va escriure en Wed, 12 May 2004 00:32:35 GMT:

>These designs also have the
>benefit of low pass filters aiding a smooth transition of Z from the
>device Z on the order of 0.5 to 1 Ohm to the System Z of 50 Ohms.

This is something I have always thought: When driving loops, very
short monopoles (VLF) or other low-impedance antennas, why raise
transmitter Z to 50 ohms, send it through the line and lower it
again to whatever required? Couldn't the amplifier be built
directly at the antenna base so _no_ transmission line is
required and couple directly the low Z at the final transistor(s)
to the low Z at the antenna?

Aside, for VLF, audio is usually transferred at 8, 4 or even 2
ohms. VLF is not that far apart from audio, only 1 decade higher.

73s

Thanx for all your help and answers, the bic pen seems to work will again
later tonight hopefully get me through to next week when the new isolators..

Thankyou

a.

2116. 5/8 wave ground plane

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-12 11:17:04 UTC
From: Larry D <larry@may2004.com>
Message-ID: <JaqdnSLsOvcJmj_dRVn-uw@bright.net>
Source record: 95367

I want to construct a 5/8 wave ground plane for 24 MHz.
I am OK with the dimensions, but I can't get a grip on what
the impedance at the feedpoint will be. Even the ARRL
antenna book hasn't been much help.

Can anyone tell me the impedance I can expect to see,
also any tips on matching it? Thanks!

Larry DiGioia N8KU

Message-ID: <c7t7io$s8$1@sparta.btinternet.com>
Source record: 95368

For a 5/8-wave vertical above ground at 24 MHz, conductor diameter 10 mm. -

Base feedpoint resistance = 110 ohms
Base feedpoint reactance = -j386 ohms
Base loading coil inductance = 2.6 uH
Coil diameter = 25 mm
Coil length = 33 mm
Number of spaced turns = 13
Wire = 14 awg = 1.64 mm diameter.

For other heights, frequencies and coil dimensions download in a few seconds
program BOTLOAD for immediate answers.

Jack:

Alleviates? NO! Reduces somewhat, maybe, and that is one of the most difficult things to get across to people with little theoretical knowledge. Even if it were the perfectly conducting sphere so loved in textbooks, impedance still exists, and the instantaneous voltage at point A will be different from point B. All you are doing is increasing the current carrying capability, so it is less likely to blow up due to a direct strike. Instantaneous voltage difference with respect to a remote reference can still rise to a gazillion volts, no matter how much copper you put in there, or how you configure it.

Years ago before they started burying all the phone drops and cabling the overhead wires, I connected my BC-348 to the phone withe a 0.005 uF disc ceramic capacitor. It gave me a VERY long wire, probabaly miles of long wire.

Worked quite well.

I haven't tried it since.

Source record: 95221

Bill,
I'm not familiar with the 'Palstar', so can't say how 'suitable' it would be. There are a number of the 'older' (used/cheap) tuners that should work fine, though. I have an old Dentron 'MT-3000' that will match almost anything you can hook to it, for example. Something of that nature wouldn't be quite the inve$tment of a 'Palstar' (maybe?). You're right, there used to be many more of the 'bread-slicer' sized variable capacitors around than now. They were used for a lot of different applications where high voltages were present (as in matching 'odd' impedances). You also have other options, changing feed line lengths to the loop for various bands. Not exactly the easiest thing to do, but it certainly will work. Or, experimenting to find a 'magic' feed line length that is a good compromise for multiband use. Ask Cecil about that...
'Doc

PS - If you happen to run across a dump truck load of those old 'bread slicers' I would gladly take them off your hands...(he said with $$$ dancing in his eyes).

2122. antenna deal of a lifetime

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-12 14:31:29 UTC
From: Alfred Gosselin <a.gosselin@comcast.net>
Message-ID: <5zqoc.77560$lk.5642980@attbi_s53>
Source record: 95222

Best offer over $100 and I am serious!!!

1 Hygain 5 el 10 meter monobander with BN-86 balun - "Long John"
1 Hygain 5 el 6 meter monobander
1 Swan 2 el tribander - TB2A
1 Swan 40-10 trap vertical - 4010V
1 Cushcraft 40-10 vertical
1 Cushcraft 10 el 2 meter monobander
1 Cushcraft 20 el (vert and horiz) 2 meter monobander
1 Alliance HD-73 heavy duty rotator and control box
Lots of coax and some masting

Now there has to be a catch??? You bet there is!! This deal has to be completed by May 23 and I will entertain offers through this weekend. Last offer must be in by 6PM EDT, Sunday (May 16), unless I get an offer that I can't refuse. Why such an offer? Well, I am moving and I am sure that my new neighbors would not appreciate all this aluminum. These antennas have provided me with years of faithful service and enjoyment but now it is time to move on to a new phase of my life. OLD AGE!! All of the antennas are down except the 5 el 10 and 6 meter antennas and I will expect you and a friend to remove them. Not a very difficult chore for 2 healthy individuals.My wife and I put them up years ago. Oh yes, where is this deal located?? About 15 miles due west of Hartford,CT. Anything else?? Yes, please don't ask me if you can have just 1 or 2. It's a package deal. You have to take them all.So, if you're looking for an antenna project this summer, look no further.
Feel free to contact me with other questions and thanks for looking,

Fred KA1KE

Why do you think the chart is "over-complicated". I have one with the
R,X values and only the to/from wavelength circles outside. I deleted
everything else from the Smith Chart program.

What I find convenient is to carry the image of the Smith Chart around
in my head. I'm more of a visual person than a formula person and that
image has helped me tremendously.

2124. cable selection for Sat. internet (6Ghz send, 4Ghz receive)

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-12 14:41:18 UTC
From: jay@webhart.net
Message-ID: <d36e6460.0405120641.152d208b@posting.google.com>
Source record: 95224

Hi,

Was wondering what the best choice for cable would be for a satellite internet
installation. (based on Direcways technologies)
It utilizes 6 Ghz for send freq. and 4 for the receive freq.

A base install uses RG6 for dish to send/receive modem (for up to 125 feet) - but the little reading that I have done about 2.4 Ghz and short runs of LMR400 tells me that there may be a better low loss solution.

Any thoughts?

Thanks

40-50 years ago, we had to lower the transmitter Z usually with
a built-in adjustable pi-net tuner.

Of course there is a current node at the end.

The end of the dipole is open circuit isn't it? Unless the laws of physics have changed since I've been in school, electrons can not flow through an open circuit. There will always be a 'current node' at the end of a dipole regardless of the length. There will also be a high voltage electric field. With high enough RF power the electric field can be strong enough to cause arcing and corona. The strength of the field will depend on the shape of the end of the dipole (rounded vs pointed), as I was properly chastised for forgetting on my other post.

Kraus (2nd edition, p. 375) gives a different answer.

Interpolating from the diagram on p. 375 (assuming length/diameter = 472) it
is about 90-j250.

Why the difference?

Larry D wrote:
> Can anyone tell me the impedance I can expect to see,
> also any tips on matching it? Thanks!

The VERT1 vertical that comes with EZNEC is 1/4WL on 40m.
It will be 5/8WL on 17m. (7.2 * 2.5 = 18) EZNEC sez the
feedpoint impedance on 17m will be about 100-j470 ohms.

A loading coil is usually installed between the base of
the antenna and the radial system. The coax braid is
tied to the radial system and the coax center wire is
tapped down on the coil at the 50 ohm point.

```
Rad| coil
Gnd-------+-////////---------------5/8WL----------------
Rad| ^
|
XMTR-----------+
```

If you don't mind a relatively low SWR of 2:1-3:1, use good
coax, a standard base-loading coil, and your tuner at the
transmitter.

There is plenty of 5/8WL information for 2m antennas
in the ARRL publications and antennas are scalable.

Z is close to +58-j138 ohms.

A small inductor of 0.88 uH in series with the antenna should provide a
pretty good match to 50 ohm coax.

The program takes into account antenna diameter. Does Kraus? And is he on
the same band? Is he at the same height above ground? What sort of ground
or radial system does he have? Have you interpolated correctly? Have you
understood what Kraus is saying? Is the loading coil in the same location?
Is the feedpoint at the same place. Are you comparing like with like?
Spend more time thinking about it.

Is Kraus infallible? Could be he's wrong again.

Who's Kraus anyway? ;o)

Reg

==========

The trouble with scaling (as from 2m down to 160m) is that antenna conductor
diameters are forgotten about which can cause appreciable errors.

I dunno, Reg. My 20m rotatable dipole diameter is about ten times
bigger than my 2m 1/4WL ground plane. Seems about right to me.

Larry, N8KU wrote:
"I want to construct a 5/8 wave ground plane for 24 MHz.----Even the ARRL antenna book hasn`t been much help."

At 1/2-wave, reactance nearly is zero and begins repeating as from zero.. With a 5/8-wave, you have a 1/8-wave connected to the feedpoint through a reactance repeating 1/2-wave line. A 5/8-wave antenna will have nearly the same reactance as a 1/8-wave. Value of the reactance depends on the characteristic impedance of the antenna and this depends on length to diameter ratio.

Resistance of a vertical antenna increases with its length until it reaches nearly 1/2-wavelength where it peaks and starts to fall. Sharpness of this resonant peak depends on length to diameter ratio of the antenna. You might expect a radiation resistance of between 50 and 150 ohms. Reactance may be between 200 and 1200 ohms. It depends on how skinny the antenna is. Fat conductors have smaller impedance variations (a lower Q).

My impedance numbers come from Capt. Paul H. Lee, USNR, K6TS`s "Vertical Antenna Handbook".

5/8-wave vertical ground-planes were once popular on 27 MHz and often used an autotransformer at the base to step up the impedance from the 50 ohms of the coax.

Best regards, Richard Harrison, KB5WZI

> The program takes into account antenna diameter. Does Kraus?

Yes. My post said length/diameter = 472 (One thing I don't like about the way Kraus wrote his book is that he gives the formula for only one part of the feed impedance (R or X) and a diagram for the complex impedance. He then refers you to someones paper somewhere for the 'complete' formula.. I have it around here but it would take 2 days to find it.)

> And is he on the same band?

In the diagram I was interpolating from the dimensions are in wavelengths.

> Is he at the same height above ground? What sort of ground or radial system does he have?

It is an infinite perfect ground plane---ground mounted. (We are talking about a 5/8 wave vertical remember).

> Have you interpolated correctly?

Probably not.

> Have you understood what Kraus is saying?

Yes.

> Is the loading coil in the same location?

No 'loading coil' in the Kraus example. He is discussing the feed point impedance. A loading coil would be either across or in series with the feed point.

> Is the feedpoint at the same place.

Since the original post concerned a 5/8 wave vertical, I assumed it is at the bottom, which is what Kraus is discussing.

> Are you comparing like with like?

Hence my question. Are we? I recall that a 5/8 wave vertical was 'close' to 50 ohms at the feed point and could be 'adjusted' with an inductance across the feed point (with the feedline at a tap perhaps?). That is the whole point is using such a 'magic number' as 5/8 wavelength. If you look at the impedance curves, though, you find that they are quite steep at this point, so a small error in length causes a large error in impedance, and some tuning will be needed. The 5/8 wave is not a 'build it and go' antenna!

> Spend more time thinking about it.
>
I have, which is why I looked it up.

> Is Kraus infallible? Could be he's wrong again.
>

=8o Oh no!!! Kraus wrong!?

> Who's Kraus anyway? ;o)

Oh, I don't know. Just some guy that signed my Master's Thesis 16 years
ago.

KJ4UO wrote:
"If I have an RG-58 coax and it is shorted at the load end."

At the electrical input, 1/8-wave back from the short, you have an inductive reactance equal to the numerical value of Zo. At 1/4-wave back from the short, you have added an open-circuit 1/8-wavelength of line to the first. This new line has a capacitive reactance equal to Zo.

The combination of equal and opposite reactances makes a parallel resonant circuit equivalent which seems a very high impedance indeed.

Best regards, Richard Harrison, KB5WZI

Partly because you used a conductor diameter about 16.5mm and Reg's
was 10mm. (Don't think I'd want to make a self-supporting element
that long and that thin, myself. Maybe 50mm at the base and tapering
to 25 or so?) That probably does not account for the whole
difference. Did you both use the same sort of "ground plane"? Height
above earth has only a slight effect.

Cheers,
Tom

>It will be 5/8WL on 17m. (7.2 * 2.5 = 18) EZNEC sez the
>feedpoint impedance on 17m will be about 100-j470 ohms.

Hi Cecil, He was asking about 24MHZ which is 12 meters. EZNEC sez a 5/8 on 24MHZ is 63-j206, more or less. As others have pointed out a lot of factors will enter into the final installed impedance.
Another matching method, for 63-j206, is feed the antenna with a 1.2 meter length of 300 ohm twinlead- 1:1 balun- 50 ohm coax. The twinlead transformer gives 43-j0. Don't tell Reg, but I did that on the Smith Chart in 48.32 seconds:-).

Best way to do this is to use telephone quad (station)\
wire between the telco demarc and the rj-11telephone
block. Phone pair will be the White, White/Blue
or Red/Green pairs. You can then use any of the unused
wires in the cable as the antenna lead. Radio signals
will be common mode on the cables, and will capacitively
couple to the adjacent pairs. No need for a direct
capacitive coupling to the hot phone pair.

> Does this effect the preformance of the antenna in that the reflector and
> directors are all connected from an electric point of view?

Provided the lengths are corrected for the boom (connected or not connected)
there is no differance in the antenna. It might make some differance if the
connection is not 100% all the time as the elements could become loose and
not be connected . YOu can get all kinds of noise on signals if the
elements become loose. That is one plus for insulating the elements.
Unless welded to the boom many elements will loosen up some in time.

>

1. Prevents the LNB converter from shadowing a major portion of the
dishes surface with loss of gain.

2. Since the angle of the received signal is offset by the same number
of degrees as the feedhorn offset, this results in a more vertically
plumb dish surface that more readily sheds snow and ice buildup.

Source record: 95249

>A endfed vertical for 40m is around 67'

No it is not. A 1/4 wave vertical for 40M is around 33'. If mounted at
ground level it requires an extensive ground radial system to get good results.
If you are talking a 1/2 wave vertical better to feed it in the center.
An inverted "L" with 33' vertical and 33' horizontal is around 67'. Still
requires a good ground.

>Could a coil be placed in the
>center of the endfed wire to shorten it to say 40'

Yes, but you need to remember the radial requirements, and if you start
sticking coils in the antenna, then the matching starts being a problem.
>This would make it
>easier for my portable QRP
For QRP and portable operation 40m-10m, a 50'-100' inverted vee fed with
300-450 ohm balanced line and a tuner. Get the apex up as high as possible.
You can not beat this for multi-band portable operation.

>the reasoning behind this design?)

Yes, these dishes are designed/intended for an off-center LNB. They
have a different radius of curvature in the horizontal and vertical
dimensions. You won't be able to place an LNB (or access-point
antenna) at an on-axis location and get a clean focus.

The reason for an off-center focus arrangement is that it keeps the
LNB or other driven element, and its support strut(s), out of the path
between the satellite and the dish. This reduces diffraction effects,
and results in a stronger signal and cleaner focus.

>I find 2 things:
>1. It doesn't really matter where I point the dish. The signal varies a
>little bit when I approach the direction of the access point, but no "leaps
>and bounds" in the signal strength between being "dead on" and way off.
>
>2. I pick up signals that aren't even in the direction of the access point.

I'd guess that this is due to a combination of three effects:

- You aren't getting a clean focus, because you're trying an on-axis
focal position for a dish which isn't circularly symmetrical. Try
re-attaching the LNB support arm which came with the dish, and
mount the access point on this arm so that its antenna is at the
location of the original LNB.

- The dish was designed for frequencies higher than 802.11b - it's a bit small (in terms of wavelengths) to get a really clean focus at 2.4 GHz. Some people have had better results using the larger dishes originally intended for use with the lower-frequency Primestar system.

- The access point's antenna is probably rather omnidirectional in at least one dimension - you're getting significant reception "off the back" of the antenna, via direct radiation which isn't being reflected from the dish.

Commercial parabolic-dish antennas for 802.11b use are usually circularly symmetrical, with an on-axis feed arrangement consisting of a dipole or (often) a two- or three-element Yagi arrangment aimed towards the dish.

I've gotten reasonably good results using a Dish Network dish and LNB support arm, with the LNB replaced by a homebrew biquad antenna and sheet-metal reflector.

Ok, fine. The frequency and size of the U channel are still needed.

Also, how are the U bolts fastening the bits together? I can think of
at least 2 ways to do it with what you've described. 1 - the U bolts
are pinning the element like a staple pins a wire, and 1 or 2 of them
could be used in that case. 2 - the elements are large enough diameter
and the U bolts small enough that the U bolts pass around the boom, and
through holes drilled in the elements. I suspect #2 is unlikely at UHF,
though.

Also what is the orientation of the channel to the elements?

In addition to the discussion[s] on focal point, the received signal gain from the 18 inch antenna is down approximately -14 dB from the 12 GHz nominal frequency for the satellite tv signals. There will be a further reduction from the off center feed [It's been 15 years since I ran the calculations and I'm too rusty at age 66 to do them now <grin>].

From old experience, I would expect somewhere around a 10 +/- ? degree beamwidth at 12 GHz and somewhere around 30 to 40 +/- ? degree beamwidth at 2.4 GHZ. So, a fairly broad pattern that you describe does not seem unreasonable. However, I invite a microwave engineer with more recent experience to comment and I'll freely accept a better analysis and conclusions.

You might want to check out the article in the May 2004 issue of QST on
ppg 28. It is for a shortened end fed 1/2 wave 80 meter antenna.

Mike

Oops. It's not circular or symmetric.
I've heard that it is a portion of a parabola, rather than a parabola in
itself, as if the oringal mounting point of the LNB were mounted in the
predicted focal point of a larger piece of metal that did form a parabola.

The proper focal point is wherever the antenna element was on the original
LNB. The frequency doesn't matter. That's still the focal point.
The next problem is knowing exactly where the antenna is in your USB
widget, so that you can put it in the same spot.

I think it's 22 degrees, but it is certainly "off". The old Primestar
dishes often looked like they were pointing at the ground, instead of into
the heavens.

> I tried rotating the dish on its axis to account for polarity mismatch (
> would this really be an issue?). No joy.

My DLink DWL-122 USB adapter improves noticeably when the orientation is
correct. I tried the face facing the WAP, horizontal and vertical, as
well as edge on, horizontal and vertical. I didn't try end-on.
For my setup the face on - horizontal was best.

> The wireless adapter can receive signals well, generally, w/o a dish, but
> because of my location, reception of the desired signal is not great.

I put my USB widget 1" in front of a 9" pie tin. The 9" pie tin isn't
really quite large enough. 1" was discovered empirically, and appears to
be good for about 6db, according to Netstumbler. It is also far more
stable with the pie tin, where without it the signal seems to wander.

> http://www.usbwifi.orcon.net.nz

His wok is a parabola. That doesn't count for you.

I was going to use a reflector like Trevor's BiQuad to feed the USB to a Dish-Dish, but my son cleaned out his garage and threw the dish away about a week before I asked for the dish ;-(.

I think the reflector behind the USB widget, painting a parabola, should be a good combination. And the right focal point for the odd-shaped Dish-dish is important.

http://www.trevormarshall.com/biquad.htm
http://martybugs.net/wireless/biquad/
http://63.142.46.238/buck/CantennaUSB.html

And my favorite site:
http://www.nodomainname.co.uk/cantenna/cantenna.htm
Where David uses a full sized USB adapter, pulling the antenna loose and sticking it through the side of a can.

I might put my mini-usb inside a can.

Actually, (gain wise), as, from memory, double the SIZE, (or conversely),
Double the Frequency, you gain 6 dB! lets see: these for 18 GHz, , lose 6
dB, for 9 GHz,
Another 6, to 4.5 GIG, and another 6 to 2.25 GIG ! total, 18 dB loss!
Now, as to the dish, IF the round one, what was stated about getting the
feed centered is true,
HOWEVER, if you have the ELEPTCIAL dish, these are made to view 2 SATELITES!
and, even
Directv is useing them!! Reason?? Has to do with "OTHER" services, like
internet connects, and
LOCAL TV feeds!! In esscence, the dish is aimed between 2 sattelites,
allowing it to "see both
sattelites at the same time. This allows aprox 2-3 HUNDERD more (local)
channels to be direct
broadcast to your home (ABCBSNBCPBS) !! These are NOT very effecient
antennas at 2.4 GHz,
but, if you place your 802.11 feed, where the original feedpoint was for 18
GHz, most likely will be
at the most effecient point. Also, buried in the RECIEVERS for satelite
Recievers, they have
aiming instructions for these dishs, by zip code, and you will note the
different pointing instructions
for them, both round and eliptical!! Hope this helps, Jim NN7K

==========

Problem solved!

I've checked the program's source code.

A perfect Earth is assumed.

For simplicity, program BOTLOAD neglects "end effect" which amounts to about 6 percent of height when antenna diameter is 50 mm.

Radiation resistance is obtained by a Simpson integration of radiation along the length of the antenna. Input reactance is obtained from an open circuit at the end of a transmission line with Zo calculated from antenna dimensions.

We have two Eznec determinations close together which average Zin = 60 - j172 ohms. I think Kraus can be ignored.

Using BOTLOAD, if antenna height is varied at exactly 24 MHz we can obtain Zin = 60 - j176 ohms. The change in height corresponds to the 6 percent end-effect.

The relatively large change in input impedance is due to the sensistivity vs length at a height of 5/8 wavelengths.

A slight further change in length will bring input resistance to exactly 50 ohms.

But as implied by its name, the principal purpose of BOTLOAD is to calculate either the number of turns on a coil or the value of a tuning capacitor, plus or minus 10 percent.

Some of my programs incorporate end-effect without it being explicitly stated. But its a tedious task to do so and is usually not worth the trouble. Radio is by far the most inexact of all the engineering disciplines. Where else can one be happy with an S-unit or two, more or less?

Hence my question. Are we? I recall that a 5/8 wave vertical was
'close' to
50 ohms at the feed point and could be 'adjusted' with an inductance
across
the feed point (with the feedline at a tap perhaps?).

Tuned to an electrical 3/4 wave...Basically, just tuning out the
reactance..

That is the whole
point is using such a 'magic number' as 5/8 wavelength.

Huh? The point of the 5/8 radiator is pattern and gain related, not feed impedance, or matching.

If you look at the
impedance curves, though, you find that they are quite steep at this
point,
so a small error in length causes a large error in impedance, and some
tuning will be needed. The 5/8 wave is not a 'build it and go' antenna!

It's pretty close to it though. All you have to do is start off with a "best guess" coil and test. If it's resonant low in freq, take turns off. One at a time, if close. If it's high in freq, you need more turns. Not really any more complicated than trimming a dipole for resonance. After building a lot of those, I can guess the number of turns needed in my head and come pretty close. Reg's guess of 13 turns is pretty close if the form is 1-1.5 inch wide. Using my built in guessing machine, I would have quoted appx 15-16-17 turns off the top of my head , if the coil is made of #12 solid wire, and wound on a 7/8 inch pipe former, "I use a piece of 7/8 inch copper tube as the former" and then taken off the form. "On those type of coils, I make them self supporting. The #12 wire is stiff enough to hold it's shape. Just connect and clamp each end of the coil to hold it in place. MK

Down-load in a few seconds and run immediately program MIDLOAD for a
complete design including number of turns on the coil. Can be made easy to
feed with a link coupling. Unfortunately, one band only.

It will certainly work and if you put the coil in the exact center of
the 1/2WL, it will satisfy the folks who claim that the net current into
the coil is the same magnitude as the net current out of the coil. :-)

I had forgotten I had changed VERT1 from tubing to #14 wire.
That was the problem with the higher impedance. With 3 inch
dia. vertical tubing the impedance on 18 MHz is 62-j190.

George, thanks for your reply. But in Webster's Dictionary:

Alliviate: To make less hard to bear; to reduce or decrease.

That's exactly why I used that word. And, after all the absolutely
invaluable help available from experts on this group, I still consulted a
Professional for the specifics of my site requirements. And common bonding
everything becomes more important than whatever impedance ground has between
any two points in the entire system. A properly bonded and grounded system
does not care what impedance or voltage is present on the system. Please
don't make me define properly.

;-) 73's

Jack.

No. The driven element can be grounded to the boom also. Again, no change, except you add a matching device. The connection is at the high current/min voltage point. Being there is little voltage at the center of the 1/2 wave elements, the boom is pretty much ignored by the antenna. Also, it's at a 90 degree angle, which further reduces coupling to the elements. My cushcraft tri-band beam uses an insulated driven element, but most of the yagi's I build have all the elements grounded to the boom. My three el 6m yagi has all the elements welded to the boom, and the whole antenna, elements, boom, even the gamma match tube, are all hard copper tubing. It's a one piece antenna. Or a plumbers delight, as many call that method of construction... MK

Doc,

If a rig has automatic antenna tuning, even like the older Kenwood TS-850SAT, how does that usually work if you have a balanced feed line? Would you still use a balanced antenna tuner in addition, or would you override the auto tune in the radio, or would the radio be able to handle it?

PS, concerning murphy's law or somesuch, I have been waiting to put my coax from the 80m OCF, in some conduit through the field to my house. I even said to myself "watch out while you mow", but there is something hypnotic about the mower and me being slightly a geezer (Doh! as I slap myself on the head), sure enough, I mowed right over it, so now I have to run an extension cord out to the field so I can do some soldering, I assume they make a female to female bulkhead connection or something, I will check at the local electronics store tomorrow, of course those connectors will not fit inside the conduit I have...etc. Sometimes I think I have the short term memory of a gnat.

Hi,
> If you are talking a 1/2 wave vertical better to feed it in the center.
Why ? A 1/2 wave antenna exhibits very high impedance on its end, but
it can be matched to any feeder by a 1/4 wave shorted stub of twinlead
or coax. This stub may be placed horizontally near ground and the coax
one may be even coiled. The antenna would be a sort of shortwave
J-pole. Its big advantage against a 1/4 wave groundplane is the J-pole
has only modest requirements on RF grounding. Lightning and static
protection are still essential, of course, but it is easy - the
shorted end of the matching stub can be grounded directly.

> >Could a coil be placed in the
> >center of the endfed wire to shorten it to say 40'
> Yes, but you need to remember the radial requirements, and if you start
> sticking coils in the antenna, then the matching starts being a problem.
If you cut the coil into halves, you will see a low (about 5 ohms)
balanced impedance there. The better idea seems to be: two identical
whips as long as possible and a matching coil between them. Another
coil (maybe 1 - 2 turns only) wound around the matching coil is
connected to the feeder. Download MIDLOAD.EXE from Reg's superb
collection http://www.btinternet.com/~g4fgq.regp/page3.html#S301" and
play with it a bit. If the total electrical length is 1/2 wave, the
radial requirements should be modest. Remember the bottom end of the
antenna will be near ground - possibly within reach of uninformed
people - and under high RF voltage !

There is 0.5 Ohm when the transistor is on but not when is it off. So the
resulting impedance should probably be more than that. ??

> This is something I have always thought: When driving loops, very
> short monopoles (VLF) or other low-impedance antennas, why raise

> directly at the antenna base so _no_ transmission line is
> required and couple directly the low Z at the final transistor(s)
> to the low Z at the antenna?

This is what I have. The amplifier is directly connected to the loop.

Here is a scope screen copy of the output of the amplifier:
http://www.fractalconcept.com/scope-screen.jpg

The C2 trace is the drain voltage and the C3 one is the 50 Ohm resistor
voltage.

The schematics is very simple:
http://www.fractalconcept.com/schema.pdf

The first one is the one that works on the scope screen.
The second one is a one that does not work at all: the torus of the 680nH
melted :(

I have a little more success by just connecting the drain to the loop
through a capacitor but it's still not good (25% efficiency)

Any idea ?

Marc

>conclusions.
>
>

For a circular aperture--a good approximation-- the gain equation approximates to :

10 log (10 D(L)^2)

where D(L) is the diameter of the aperture in wavelengths.

If the dish is 0.45 meters, we get the following for the gains (assuming (naively) 100% aperture efficiency):

Freq gain
12 GHz 35 dB
2.45 GHz 21 dB

Thus Dave's accurate answer.

Going off-axis lowers the aperture efficiency anywhere from 1-3 dB from ideal, although it usually is only 1 dB or so down from the losses of vignetting from the (centered) feed. So you're probably seeing about 18+ or so dB of gain.

The FWHM of the beam is approximately

57/D(L)

degrees. So at 2.4 GHz this is about 16 degrees to the 3 dB points. Possibly broadened by the feed arrangement and dish curvature , but the 30-40 degrees sounds a little high Dave.

Not a microwave engineer; will a radio astronomer do:-)?

Oh, and one other consideration-- your 802.11 most likely , (for the want
of a better word)
is "Omnidirectional" which is a lousey way to illuminate a dish!! A dish is
much happier when it
is illuminated with a beamwidth of say 60 degrees (for the sake of
arguement), any other power
outside that beamwidth isn't even hitting the dish (wasted energy, further
decreaseing the gain)!
Translation: if even a horn ,or a small yagi, ect. would make a much more
effecient feed than a
point source (radiating in ALL directions) You are starting with little
gain, and overlapping (wasteing
power) that is 2 strikes against you for directional gain!! Jim NN7K

I Sent:

Best offer over $100 and I am serious!!!

1 Hygain 5 el 10 meter monobander with BN-86 balun - "Long John"
1 Hygain 5 el 6 meter monobander
1 Swan 2 el tribander - TB2A
1 Swan 40-10 trap vertical - 4010V
1 Cushcraft 40-10 vertical
1 Cushcraft 10 el 2 meter monobander
1 Cushcraft 20 el (vert and horiz) 2 meter monobander
1 Alliance HD-73 heavy duty rotator and control box
Lots of coax and some masting

Now there has to be a catch??? You bet there is!! This deal has to be completed by May 23 and I will entertain offers through this weekend. Last offer must be in by 6PM EDT, Sunday (May 16), unless I get an offer that I can't refuse. Why such an offer? Well, I am moving and I am sure that my new neighbors would not appreciate all this aluminum. These antennas have provided me with years of faithful service and enjoyment but now it is time to move on to a new phase of my life. OLD AGE!! All of the antennas are down except the 5 el 10 and 6 meter antennas and I will expect you and a friend to remove them. Not a very difficult chore for 2 healthy individuals.My wife and I put them up years ago. Oh yes, where is this deal located?? About 15 miles due west of Hartford,CT. Anything else?? Yes, please don't ask me if you can have just 1 or 2. It's a package deal. You have to take them all.So, if you're looking for an antenna project this summer, look no further.
Feel free to contact me with other questions and thanks for looking,

Fred KA1KE

2185. 80 m short end feed

The article in the May 2004 issue of QST on ppg 28. It is for a shortened end fed 1/2 wave 80 meter antenna. How well does this antenna perform.

Will it be an effective multiband antenna for 80m - 10m? I have no way of modeling the antenna and am not sure how to model it. Can somebody model it and let me know how it works as a multiband? Will performance change if it is made into an inverted "L" with the vertical section about 10-20ft high and the horizontal section about 20' off the ground. I am interested in NVIS on 80/40 and dx on the higher bands.

Several posters have recommended a simple series coil for matching.
But of course, you'll never get lower than the resistive component of
the feedpoint impedance that way. At least one suggested a tapped
coil, and that can give you a good match and has the advantage of
DC-grounding the lightening ro...I mean radiating element.

Another alternative is a shunt coil to ground and a series capacitor
off to the feedline; that gives you the grounding and also lowers the
low-frequency coupling to the feedline. If Reg's suggested 110-j386
is correct for your case, you can get a match to 50 ohms at 24MHz with
a 1.1 microhenry shunt coil and 25pF series capacitor. The Q should
be around 5, not much higher than the antenna itself but can lead to
fairly high voltage across the cap. Don't leave it exposed to rain
:-) (That's an advantage of the tapped coil: less suseptable to
weather problems.)

But beware...the range of impedances I've seen posted suggests your
installation may be somewhat different.

Cheers,
Tom

18 inch is much too small a diameter @ 2.4 Ghz for gain or directionality.
24 inch is "almost" workable, but it is easier to use a corner or yagi.
You can use a omni type generic antenna, and chicken wire, or hardware cloth
as reflector on a corner antenna.

Check your equations or gain, diameter with wavelength/frequency on the
parabolic.
If you aren't getting 10 dB out of it, it is not worth it. (you can get an
easy 6 from a simple corner reflector)
Illumination from the feed is important, should be 10 dB down at the edges.
Most likely it is not being fed at the right angle either, related to your
F/D ratio.

Note: lots of lame parabolic on the 802.11b market, too. (like a parabolic
on terrestrial TV)

Antennas are Fun! This is the place to post your questions.

Hi Marc,

There are a number of questions.

First, how do you compute efficiency?

Where on the schematic are these scope connections?

What is your design source for this schematic, or if original, what
drove you to select the reactive components you did? The series load
on the drain does not resonate at 8MHz and is not particularly matched
to either the FET or the 50 Ohm load.

What is the inductance of the loop? Alternatively, what size is it?
This last is more important because it subsumes the radiation
resistance that must be known to perform any efficiency computation.

The two circuits are very, very different from each other to be
achieving the same purpose. The 50 Ohm resistor, as an equivalent
load appears to be grossly in error.

By all appearances of the magenta trace, you are running Class B or a
very long Class C. This is not a hallmark of high efficiency.
However, not knowing where this trace resides in the circuit, this is
simply a guess.

Here is a rule of thumb that you can take to the bank. If an shortened
80m antenna has loading coils, it will not perform well on the higher
bands. Why? XL=2*pi*f*L - do the math. XL *increases* proportional
to frequency. For antenna efficiency, you NEVER want XL to be more
than you need. And there's something called self-resonance where
XL=self-XC, a terribly lossy condition where the coil current is
sky high.

This is one of tricks that Mother Nature plays on us hams. XL goes
the "wrong" way with frequency but (pardon my Russian) "tough shitsky",
that's the only way it goes.

Could a loading coil be used more like a trap?

The resistive part of the Z of a 5/8 wave will closer to 50 ohms than it will be for a 1/2 wave, but
in most cases will be higher than 50. You may be thinking of a vertical close to 3/8 wave which
will be 50 -jx. The -jx (capacitance) can be resonated with a +jx in series for a 50 ohm feedpoint.

The power in the load divided by the power used by the amplifier.

> Where on the schematic are these scope connections?

?? The C2 trace is the transistor drain voltage and the C3 one is the 50 Ohm
resistor voltage (not the ground ;-).

> What is your design source for this schematic, or if original, what
> drove you to select the reactive components you did? The series load

I looked at a lot of class E app notes and picked one.
I started with approx values and changed them incrementally to try to have a
better result.

> What is the inductance of the loop? Alternatively, what size is it?
> This last is more important because it subsumes the radiation

The loop is 65x25mm

> The two circuits are very, very different from each other to be
> achieving the same purpose. The 50 Ohm resistor, as an equivalent
> load appears to be grossly in error.

Yes. This is the problem. The first one was to test if I was able to make a working class-E amplifier. The second one is really bad. I have a third one where the loop is connected in place of the resistor which is somewhat better but still not good.

> By all appearances of the magenta trace, you are running Class B or a
> very long Class C. This is not a hallmark of high efficiency.
> However, not knowing where this trace resides in the circuit, this is

The C2 trace (the drain voltage) looks like the one expected for a class E IMO.

Ken, we may be talking about two different things, but a 3/8 wave vertical has inductive reactance, and the R component is no where near 50 ohms. A 2/8, or 1/4 wave vertical has no reactance, shorter has -jx, and longer, as in 3/8 wave has +jx.
A .26 lambda vertical has about 50+j43 impedance, and the +j43 can be cancelled with series 154pf at 24 MHZ. This is a common method of matching a 1/4 wave vertical to 50 ohms. Make it a little longer to look inductive, 50+jx, and cancel with a series cap.
According to all the theory I know on this stuff a 3/8 wave vertical will not be as you describe.

McFadden responds! Hope he can integrate some of this into that
periodic posting.

To: Dan Jacobson <jidanni@jidanni.org>
From: Bill McFadden <billmc@agora.rdrop.com>

>http://www.rdrop.com/users/billmc/phone_antenna is built around
>a ".01uF capacitor", but what kind? Are big .01uF capacitors better
>than small ones etc.?

It doesn't matter much, but a ceramic capacitor is probably going to be the
best (and cheapest). A voltage rating 250V or higher would be good since
the ringing voltage on a phone line is around 90 V RMS.

>Is .01uF critical or is there actually a range that is acceptable?

The value isn't critical. Anything within a factor of 3 (.0033uf to .033
uF) should be okay.

>Also the "RF connector" isn't clear. What are examples of this "radio
>frequency connector"?

The RF connector is whatever kind of plug fits the antenna input on your
receiver.

>Perhaps just coax to alligator clip?

That's how I made the first one. It was one clip lead from the phone line
to the capacitor, and another clip lead from the capacitor to the whip
antenna. Worked okay.

>Is the 50 ohm coax critical? How about a plain wire from the capacitor
>to the radio's telescoping antenna? Should the telescoping antenna
>still be extended, or retracted?

You only need coax if you're feeding the coax antenna input on the
receiver. You can use the whip antenna, which doesn't matter whether it's
up or down. If you get a lot of interference from nearby broadcast
stations, you'll need to use coax and one of the filters in the article.
50 ohm coax isn't critical. 75 ohm coax (TV coax) is often cheaper and
better shielded.

>How do we know if our phone line antenna is working properly? Should
>time signals on 5000, 10000 khz etc. jump out in perfect clarity?

You should get stronger signals than you would with the whip antenna alone.
If the signal level drops when you disconnect it, then it's working.

>Certainly there must be a slight advantage between one of red and
>green vs. the other... or might we not even bother comparing, as they
>are certain to be the same?

I didn't notice any difference, but it was easy to try both.

>By the way, I found a .01uF capacitor that the capacitor numbers web pages
>don't seem to decode: 103K PE50. I can't figure out what the PE50 or
>PE5Q means.

50 is probably the voltage rating (50V). PE may refer to the dielectric
material, but I don't recognize it.

>Lastly, the article has some spelling mistakes, e.g., lightening arrestors.

Fixed.

>The loop is 65x25mm

Hi Marc,

Yes, this appears to be extremely problematic. The radiation
resistance of this loop is on the order of 30 nano Ohms. For you to
achieve a 50% efficiency in radiating the input power, no component in
the resonant loop must have an Ohmic resistance greater than this.

In other words, you don't stand a chance. What coupling that you are
getting is probably more capacitive or inductive than radiative.

The radiation resistance of a loop rises or falls by the 4th power of
its ratio to the wavelength of excitation. Double the radius and you
will multiply the radiation resistance 16 fold.n What this says, is
that the radiation resistance is overwhelmed by conductor loss (even
if only micro Ohms) that is turning your power into heat.

2196. TVI/ W3EDP question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-14 00:42:10 UTC
From: Paul Logan <paul.logan4@btinternet.com>
Message-ID: <c814l1cjs1@sparta.btinternet.com>
Source record: 95199

Hi all,

ive been having a bit of a TVI problem with a neighbour whos receiving set up isnt up to scratch (Receives me great though and seems to transmit line timebase sound very nicely too)

Anyhow I tried an experiment using an end fed wire the W3EDP - 85 feet of wire tuned against a 17 feet counterpoise and said neighbours tv went nuts. I was feeding the wire into the shack and using a tuner at the window frame with the counterpoise dropped out the window from the second floor- dangling with no connection to anything. Now on taking away the counterpoise and adding a much longer counterpoise which runs underground the interference problem cleared up.

Can someone explain to me exactly what was going wrong- was the counterpoise radiating like mad with no path to ground?.

Also can someone suggest some simple antennas which work well against TVI?.

>
>Can someone explain to me exactly what was going wrong- was the counterpoise
>radiating like mad with no path to ground?.

The neighbor's TV might have been picking up direct radiation from the
counterpoise (yes, the counterpoise is going to radiate - it's half of
the antenna!). It's possible that the counterpoise was dangling close
enough to some household metal (e.g. a gutter, or the chickenwire in a
stucco wall) to be coupling a lot of RF into the building structure.

It's also possible that with this counterpoise you had a significant
antenna imbalance - enough to be creating an "RF in the shack"
problem, with RF appearing on your rig's chassis and coupling into
your house wiring, and getting into the TV set via the power mains.

>Also can someone suggest some simple antennas which work well against TVI?.

In general, what you want to do is minimize the amount of RF which
gets into the receiving set via any path:

- via the antenna,
- via the power lines,
- via direct pickup to the chassis

This will reduce the problem of "fundamental overload", where the high
RF voltage levels from your transmitter force the RF circuitry in the
TV into nonlinear operation. TV sets _should_ be designed to deal
gracefully with strong RF signals outside of their operational
band(s), but they often are not.

One good way to minimize RF pickup by the TV is to simply increase the
distance between your own antenna, and the TV and its antenna and
power wiring. Also, use a balanced antenna (e.g. a dipole), with a

good balun at the antenna feedpoint - this will minimize the extent to which your feedline radiates RF.

I've seen a claim that the Cobbwebb antenna (a dipole bent into a near-circular shape, with the tips of the wires only a foot or so apart) tends to cause less TVI than some other antennas... allegedly because having the two high-voltage ends fairly close to one another causes the resulting RF voltage fields to cancel out fairly rapidly as one moves away from the antenna. I haven't experimented enough with this sort of antenna configuration to know if it's true.

Other things which can help include:

- Install a high-pass filter right at the TV's antenna terminals. This will block out the lower-frequency RF from your transmitter, and help minimize fundamental overload in the TV's tuner.

- Add a ferrite RF choke to the TV's power cord, as close to the TV chassis as possible. This will help minimize RF pickup via the power mains and the TV's power cord. If the TV has wires to hook it to external loudspeakers, or to other A/V components, clamp some ferrites onto these wires as well.

The comments about the dish being a portion of a parabola appeared long
before the multi-LNB dish became available.

In any case, using the original LNB location as the focus would be a good
thing to try.

I took the probe apart and looked at the bands around the diodes, wrote them down, and have now lost the note. In about two days, I'll have a chance to look again and I can either email you or post my findings here. OTOH, maybe it would be better to move this to the science.electronics.equipment forum?

> Anyone have a schematic of the boards in the probes?
> I think I have a broken capacitor in one as well as bad diodes.

See a.b.s.e., subject HP 8405 Probe Schematic. I posted a portion of the schematic I have. Unfortunately, the diode types are not indicated. The B.O.M. I have shows HP in-house numbers, I guess, so I didn't learn anything from it.

The SMT transistor in the probe is a 2N3379. So far, I have found one bad transistor and a bad diode in one probe and two bad diodes in the other probe. As I recall, searches on Mouser and DigiKey suggested replacements were 1N270 silicon equivalents.

I probably don't have an ice cube's chance in hell of getting my 8405A fixed.

> Or, would anyone have replacement boards for the probes?

I think the probes are the weak link in this fine instruments heritage. The manual profusely warns about applying voltages in excess of 2VAC or 50VDC. I'd bet excess AC is responsible for blowing the FET while excess DC blows the input capacitor *then* the FET.

I'd wager you won't find any replacement boards. I hope I'm wrong. And, if you do, please let me know.

Yes, this is exactly what I want to do : Inductive coupling.
Maybe you didn't see my first posts, what I want to do is transmit 3W of
power by induction over a 12mm distance.

I AM DOWNSIZING MY EXISTING STATION, AND HAVE THE FOLLOWING ANTENNAS FOR SALE:

1-KLM(NEW) 17M 3 ELEMENT YAGI ON AN 18' BOOM
$275 OBO

2-CUSHCRAFT 215WB 15 ELEMENT 2M YAGIS ON 15' BOOMS
$175 OBO

2-KLM 432-30LBX 30 ELEMENT 432 MHZ YAGIS ON 17' BOOMS
$200 OBO

1-KLM 220-22LBX 22 ELEMENTS ON 220 MHZ
$200 OBO

PRICES DO NOT INCLUDE SHIPPING
ALL ACTUAL SHIPPING CHARGES WILL BE PAID BY THE BUYER(NO INFLATED SHIPPING CHARGES).

Hi Rob
My SteppIR antennas have survived winds that destroyed nearby trees FWIW.
I think the claimed wind survival ratings are realistic.
Ice does not change the antenna's electrical behavior;
The elements are inside a fiberglass tube.
The elements can be fully retracted.
If the fiberglass tube does fail it can be cheaply replaced.
I'm upgrading my 3 to a 4.

> be as you describe.

It shouldn't be too far off. The usual method of tuning a 3/8 vertical
is also by using a series cap to tune out the reactance. Quite common
on 160m, etc where people run the "extended" inv L's that are 185-190
or so ft long. I've used them here, and with a series cap, the SWR was
quite low. The 3/8 impedance is higher than a 1/4 wave, but not enough
to really hurt things, or to make a l/c matching device needed. MK

This is what I ran when I had my 40m GP up. It worked both 17m and
40m.
My old elnec model of that antenna showed appx 48.4-j213 ohms on 17m.
But I had sloping radials. Maybe that made a difference. I used an
ungrounded series coil to tune for 17m, and the SWR was very low. I
had a 24v DPDT relay that I used to bypass the coil for 40m use.
Otherwise, it would be resonant about 6.9 mhz. I had the transformer
here in the shack, and when I changed bands, I would just plug, or
unplug the transformer from my power strip. MK

2207. Who has an ideal horizontal dipole for HF?

So who actually has the space and resources to set up an ideal
horizontal dipole on HF with the full length and height as specified
in all the formulas? Wouldn't it be cheaper and easier to set up a
vertical if you could install something that high off the ground?

The only thing I've seen personally that looks like it meets the ideal
is a small station tucked into the northeast cloverleaf of an exit off
Interstate 93 near Boston, MA, and the station appeared to be a marker
for Logan. Anyone have any personal, real-life experience with a
full-size, full-height HF dipole? Is it worth the cost?

Jack.

Sorry. I mispoke on that. The 3/8 wave will indeed be inductive. However its resistance will be
closer to 50 ohms than it would be for a 1/4 wave. A 1/4 wave would have a resistance of 37 ohms.
I'm not sure about your 50 + j43 for a 0.26 wave. Is that from EZNEC? With what kind of ground?

I didn't take the time to model the 3/8 wave. Sorry.

Ken

Hi Marc,

Then this returns us to the native Z of the source, the FET, and the
sink Z of the load AFTER the link. Your link shows a 1:1 coupling (as
best I can tell) and it follows that the load should be on the order
of half an Ohm. It also follows that the characteristic Z of the FET
load should also exhibit this value (it does not) as well as the
coupling circuitry to the link.

Move the primary loop back into the Drain lead to the positive rail
path, and connect the 2200pF cap (which may be too much) from the
Drain lead to ground path. The other circuitry is superfluous. The
characteristic Z of this load is roughly equal to the FET; and as the
FET on time is roughly 120ï¿½; and depending upon coupling, then you
might find 60 - 80% efficiency. It will require some tuning as the
Bandwidth will be 1 or 2 MHz around resonance. If you want some other
actual load resistance other than half an Ohm, then you need to boost
the transform ratio (it works by the square of the windings ratio).

Give this a try and report your findings.

Hi Mark,

Yes, the significant difference. I have always endeavored to build
5/8'ths with an offset dipole fashion either with sloping radials, or
elevated feedpoint on a metal mast that terminated in a ground field
(radials). As this is also the basic structure of the sleeve dipole
(grounded at the bottom), using coax with a ground tap to the shield
about quarterwave (a guesstimate) from the feed made it easy to
achieve.

Hi Jack,

There is no such thing. Full size and Full height for a band that has a frequencies spanning 15:1 is a contradiction. One antenna must be either significantly fuller sized or fuller heighted at some frequency, or suffer at another frequency as lesser sized or lesser heighted for the same reason.

You want a 10M dipole antenna up half a wave for 160M? Is half a wave full height? Is a 10M dipole full sized?

Describe your needs first, and then ask what would be reasonable.

I regret that my message was insufficiently specific. I didn't say
"all-bands HF", and I assumed that the potential respondents would
know that I knew that no single dipole is ideal for more than one band
(well, more than one *frequency*, but one band is close enough).

Richard> You want a 10M dipole antenna up half a wave for 160M? Is
Richard> half a wave full height? Is a 10M dipole full sized?

I am interested in people who have first-hand experience with a
full-length dipole mounted at the full height for any particular
band. A 10M dipole is full-sized if it's the full length and mounted
at the full height. Ditto for 160M.

Richard> Describe your needs first, and then ask what would be

2215. Re: HP 8405 probe repair

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-14 21:38:14 UTC
From: Gary Schafer <gaschafer@comcast.net>
Message-ID: <n1faa0h1ekbect6peg2ejofed7tk70mt58@4ax.com>
Source record: 95218

Hi John,

Thanks for the info. Also thanks to Richard for the link to sphere.
They told me that people that have replaced those diodes used 1N5711.
They are schottky diodes. Sphere wants $3.00 each for them and digi
key has them for 39 cents each.

I drug my probes out that I hadn't looked at in several years. I did
find my manual and it does have a schematic of the probes but gives no
part numbers for the diodes or the FET.

In looking at my probe boards one has diodes that have numbers 392
717. They are the input diodes. The other set at the FET input have
numbers 393 717. I don't know if they are original or replaced.

The other probe has diodes marked HP on them and color bands. The
input ones have yellow, green, gray. The ones at the FET input have
yellow, violet, blue. Don't know if original or replaced.

I see the input capacitor on one probe has been replaced and the 100k
resistor.

I checked the diodes with a meter and they all seem to have proper
forward drop (around .3 volts or so) and high reverse reading. Maybe
they are not bad? The problem may be the FET?

Haven't worked on the thing in years. Sure would like to get it going.

>See a.b.s.e., subject HP 8405 Probe Schematic.
What is a.b.s.e. ?

How did you check the FET to find out it was bad?

The sphere site has some HP house number cross references if you have
some HP numbers.

Wonder how you found the FET part number 2N3379 ?

I have run across several people with 8405,s with bad probes. Would be
nice to figure out how to get them going.

To email me direct make address garyschafer.

Thanks for your help

Years ago before they started burying all the phone drops and cabling the overhead wires, I connected my BC-348 to the phone withe a 0.005-uF disc ceramic capacitor. It gave me a VERY long wire, probabaly miles of long wire.

Worked quite well.

I haven't tried it since.

Hi Jack,

This is still inspecific. "Full height" is actually meaningless.
Let's look at a 40M dipole antenna and choose a modest 20ï¿½ launch
angle to compare against.
5M over real ground:
-2dBi
10M over real ground:
1.29dBi
15M over real ground:
3.75dBi
20M over real ground:
6.27dBi
25M over real ground:
8.08dBi
30M over real ground:
7.67dBi
35M over real ground:
7.1dBi
40M over real ground:
7.52dBi

Well, let's see - best gain is NOT at any cardinal point such as
quarter wave, half wave, three quarter, nor full wave above ground ANY
of which "could" be interpreted as "full height."

This exercise is easily within the limited feature set of the free
distribution of EZNEC.

Hi Gary,

Science and technology has marched on nigh these 30 or 40 years after
production. Shop for good components and simply do it. Your greater
task will be proving it works correctly irrespective of pedigree of
the part number.

How nice, Im broke, got no money, my ***&# ex-wife even took my house dog.
I need a stuff to make me happy again, accepting donations for my favorite
charity
"Me"

NY State says I only keep 1% for the actual charity and have a partner
write up 99% of the rest of the loot for my administrative costs. Then we
cook the books again and spend what we sold on ourselves,

"It's far too easy for anybody to set up a charity, get tax-exempt status
with the IRS, do very little of anything charitable and get away with it.
**Is not what's illegal, but what's legal - and what people can get away
with in the name of charity**
They can get away with giving 1 percent to the cause," and pay themselves 99
percent for administrative costs
Charities get protection under the First Amendment, this has resulted in a
nationwide plague of newly established charities, doing little good but
considered legitimate.

ITS A HUGE EPIDEMIC IN NEW YORK, SCUM LIKE THIS MAKE's ME ILL

Thank you for posting this; it's /wonderful/!

Now, if he wants, I can think of another feature that might
increase the auction price.

Offer a double-your-money-back guarantee.

If the purchaser can prove absolutely that no aliens have ever
heard the broadcasts, that'll double etc etc.

If the bids don't go any higher, that would be $2.50.

(But I'd /really/ like to see the conclusive proof!!)

Well, as long as the design matches your construction technique and boom. ;) If not, it may be far from working well.

VHF and up yagis have to be made just as specified in construction articles, including element diameter and taper, element mounting method, and boom diameter. If not, they can end up performing quite differently than what you would expect.

The higher the frequency, the more critical things become. At 432, for instance, we use a length tolerance of .5mm or better on element length. Cut to just a bit too long, and then carefully file to length. Then chamfer the tips.

We were picky, because we were making EME antennas for arrays, and very long boom test antennas for antenna range competitions.

And a hint on old VHF/UHF yagis - Scothbrite the elements after you test the antenna and test it again. We found it worth about .4dB on an antenna only 2 years old.

alt.binaries.schematics.electronic

> How did you check the FET to find out it was bad?

With a DVM. The schematic shows an N-channel junction FET. It should read
like a diode with the + lead on the gate and the - lead on the source. It
should show open with the leads reversed. It should show open with the +

lead on the drain and - lead on the source with the gate connected to source. Mine had reverse gate leakage.

> The sphere site has some HP house number cross references if you have
> some HP numbers.
>

They're not available to me right now.

> Wonder how you found the FET part number 2N3379 ?

The part number was stamped on the FET. I used a magnifying glass. Keep in mind that the FET may have been replaced by the previous owner.

> I have run across several people with 8405,s with bad probes. Would be
> nice to figure out how to get them going.

Yes, it would. You do know that the little probe boards unplug from the probe body, right? If you have a working probe on a working meter, you could try repairing the broken probe and try it on the working meter. I'm going to do that as soon as I can get the time.

> To email me direct make address garyschafer.
>
> Thanks for your help

Jack,

Leaving out the question of "full height", I found that a 20m dipole at 55 feet was outperforming a Junior tribander at 40 feet for distances beyond 2000 miles. Broadside to the dipole, of course.

Did you notice that he also had some audio (30 minutes?) of
aliens?

I'm /almost/ tempted but with the way it's been so far this
Spring, it'd prolly sound like my neighbors <sigh>.

Richard> Hi Jack,

Richard> This is still inspecific. "Full height" is actually
Richard> meaningless. Let's look at a 40M dipole antenna and choose a
Richard> modest 20° launch angle to compare against. 5M over real
Richard> ground: -2dBi 10M over real ground: 1.29dBi 15M over real
Richard> ground: 3.75dBi 20M over real ground: 6.27dBi 25M over real
Richard> ground: 8.08dBi 30M over real ground: 7.67dBi 35M over real
Richard> ground: 7.1dBi 40M over real ground: 7.52dBi

Where did the twenty-degree launch angle come from?

Richard> Well, let's see - best gain is NOT at any cardinal point such
Richard> as quarter wave, half wave, three quarter, nor full wave
Richard> above ground ANY of which "could" be interpreted as "full
Richard> height."

I'm not familiar with twenty-degrees as any particular canonical
value. As for what I meant by "full height", one-quarter wavelength
minimum should serve.

Richard> This exercise is easily within the limited feature set of the
Richard> free distribution of EZNEC.

I do not doubt that your calculations are within the capabilities of
EZNEC. However, I'm more interested in real-life experience, not
computer-generated simulations.

Hi Jack,

20ï¿½ serves as well as any and at least offers a basis of comparison.
This again turns to the matter of the inspecific. You cite no
particular application (DX v. NVIS) no particular band (that is
heavily swayed by ground given ground characteristics vary over
frequency) and offer a quarter wave height as "full height" which by
most standards is generally accepted as mediocre at best where half
wave height (twice full height?) offers better performance (which is
borne out in testimonial) and where higher sometimes offers worse
performance (also borne out in testimonial). Such issues are easily
isolated and compared through modeling and are consistent with
experience.

I worked at a station in Alaska that had a big antenna farm. The
station was designed to communicate with aircraft over distances from
zero to thousands of miles. We had very few limitations over what we
could do or build with unlimited space, and had two rhombic's for
communicating with two flights that took the same track every day.
Communication was mostly CW five letter group encryption. The
transmitters and receivers were separated by 20 miles or so.

The operators could choose which transmitter/antenna combination gave
them the best performance. The dipoles seemed to be the preferred
antenna. The rhombic's (the king of HF antennas) were seldom used,
probably because of the radiation pattern. The antenna is the most
unpredictable part of any installation.

I was the guy that tried to neutralize the big triodes, so you know
that was a while ago. (1950's). The globe was about the size of a
volleyball.

A fractal antenna is just another antenna that uses lumped inductance to
shrink the size of the antenna along with destroying the radiation pattern.
The arrl has a nice explantion of why antennas radiate on their web site.
Aplly this info to fractals and small coils and it is easy to see why they
dont work worth a hoot.

Larry, its been a while since I built one but I usually wind an 1/8 to 3/16wl of wire on my matching coil and feed this in series with as one would a base loaded antenna then start triming the coil for lowest SWR. I have one I built like that now on 10M SWR is about 1.5:1 . Cant say for sure but think the feed point impedance is above 50 or about 75 ohms at resonance. Have built these using the same technique for 6 and 2 . Seems like the impedance on these can vary quite a bit depending on the materials you build the antenna from. Thicker materials seems to give a lower impedance and a better match to 50 ohms. Ive never really gone into what was going on with the antenna that much and may be all wrong but right or wrong my way of doing it seems to get the job done for me. Perhaps some of the gurus around here would like to provide some more insight.

If you run a full size dipole, "I prefer coax fed in general", you
have a full sized dipole signal with very little losses. Well, unless
you have 500-1000 ft of coax... What more can I say... The antenna
cost is cheap. Wire and coax. I'm on a city lot. I presently have
160m,80m,40m dipoles up in parallel. Fed with one coax. The 160 dipole
is in a Z layout to fit the lot. The 80 and 40 are in straight lines
as normal, but spaced apart a good bit. Myself, I don't use anything
but full size coax fed dipoles, unless it's impossible. As far as
single band dipoles go, anything less is a step down as far as I'm
concerned. Loss wise and also ease of use. No tuner, no weather
hassles, etc...When I switch bands, there is nothing to do but key the
radio. MK

I thought a 1/2 wave dipole was "the standard". Standard meaning the traditional use of the dipole for efficiency and common use. I did not know it was a significant compromise from a full wave length long antenna which would be impossible to install in most backyards when you talk about 60 meters or higher. If a full wave length dipole is common I never see references to it either.

Check out Mosley antenna's. They been around along time and I have
TA-33 tribander up at 75 feet for 20 years. Bought it used and
estimate its 30 years old. QTH is southern New Jersey, not the most
severe WX but over the 20 years its seen some tough summer storms.
Check out there web site. I forget the address but you can find it
with a search.

Hi Group,

Many thanks for the input with the open and shorted transmission lines.

On another subject, F-connectors are used for just about everything video, with RG-59 being 75 ohms is the F-connector designed for 75-ohms or can I use this type of connector with 50 ohm systems?

2253. Anyone Using MFJ-1538 QUAD BAND VERT ANTENNA(6/2/220/440)

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-16 04:47:51 UTC
From: "Dennis B.Sheaffer" <wy3f@dejazzd.com>
Message-ID: <nq-dnZaY85Xpbzvd4p2dnA@dejazzd.com>
Source record: 95306

Hello,Im interested in hearing from users of the NEW MFJ-1538 Pulsar
quad
band antenna that covers (6 MTRS,2MTRS,220MHZ & 440MHZ)
I use a Comet GP-15 now for 6/2/440. Over the winter I tried 220mhz
band.I use the mfj 921 tuner with the Comet GP-15 and it does so-so
on 220.I think maybe the MFJ-1538 would be better and I would have
better efficiency on 220mhz.
This is the only quad band base antenna made for 6/2/220/440 bands,so
it makes me a little leery on performance since Comet & Diamond do not
have a model like this,so I would like to hear reports from other users.
A local ham friend just got one and I went over to his place to check it
out,and it looks alot like my Comet.
Can this antenna be tuned for 6 mtrs like my Comet,I didn't see A set
screw for the tuning rod after the 6 mtr coil/radiator.
My ham friend didn't get it mounted yet outside and he said he is
in no rush either,so I can't get any reports on it yet,like how
is the swr or bandwith,And most of all performance.
I don't want to loose 6 mtrs while gaining 220 mhz.I enjoy 6 mtrs too.
Is this a real VHF/UHF antenna break through,and wondering if we will
see a mobile version?
Some may ask why not put up a separate 220 antenna? I have restrictions
1 for hf ,and 1 for vhf/uhf limit only 2 antennas.
Any users using the MFJ-1538 quad bander please respond,I would be
interested in hearing ur likes and dis-likes with this antenna.

Hi OM,

It would seem to me that the connector is in large part simply a
connecting shell where the line itself does the chore of mating to a
rather unsubstantial socket. Undoubtedly these things are intended
for low power, low physical demand applications. I suppose you could
force-fit them to rg58, or just use RCA connectors and skip the
tedious threading.

You would have trouble physically doing it. Remember, you need coax with a skinny solid center conductor. There is such RG58, but the shield diameter is too small. It might be possible to use 8X if you cut off part of the strands that make up the center conductor, and tin the remaining ones to make a rigid conductor.

Hi, the F-connector is 75 ohm, and I have had to mate it to PL-259 to connect Belden 9913 before. This required the awkward addition of an F-to-BNC then BNC-to-SO-239 connector. The line loss added to this arrangement was probably significant, but the reason was to adapt an inexpensive log periodic beam antenna. Although manufacturer claimed transmit capable, and I did test this on vhf-marine bands, the mismatch of connectors should be used for receive-only.

??? Using connectors that don't maintain the characteristic impedance of the transmission lines they connect _will_ produce undesired effects. The effects may be negligible to amateur radio operators used to operating transmitters into rather high mismatches, but they would never be tolerated in most professional operations, including high-power broadcast systems.

Years ago a common impedance for rigid transmission line used in broadcast systems was 51.5 ohms. Later the more common value was/is 50 ohms. While a mechanical adapter was available to allow connecting a 51.5 ohm inner conductor to 50 ohm inner conductor (SWR= 1.03), better installations installed an RF transformer section at these interfaces.

A 1.1 SWR at the input of a TV transmit antenna using ~500 or more feet of transmission line will produce a visible "ghost" in the transmitted picture, as seen by a careful observer. At 1.25 SWR it can be seen, and will objectionable to almost everyone.

To save the trouble of calculating it I'll take a guess. A connector less than 1" long of impedance 51.5 ohms in a 50 ohm system will NOT produce an SWR of 1.03:1 or anything anywhere near to it at frequencies less than 1000 MHz.

A 1" long connector WILL produce an SWR of 1.03:1 around 3 GHz but no worse. If you can reliably measure it.

What matters is the ratio of connector length to wavelength along the line.

For the same reason, at HF, bringing the two wires of an open wire line close together for the purpose of drawing them through a single small hole in the wall, will not produce any noticeable effect on line performance.

Reg.

Gernic antenna, if it is within 3:1 vswr then it is matched fairly well.
Gain is directional, this one should have a pattern that changes as one
moves up in frequency, more lobes.
good one to check on on EZNEC (demo free on internet)
Low Freq need a good ground.
Also this type of antenna was used in the 20's and 30's, and on the ships at
sea.

According to a QST review about 20 years ago, the B&Ws are comparable
to a standard dipole from 20 meters and up; much less efficient than a
standard dipole, below 20 meters.

Yep, a short 80m antenna does ok on 20m. The Military, in their quest to get a signal out, in the smallest space possible devised a scheme that used a very inefficient antenna. From what I have read, it was a 20 kw transmitter with matching auto-tuner that tuned from 2-30 mhz.
One makes up for the -6db loss on 4mhz with brute force. The B&W has 6db or more loss on 80m. As a ham, I hope my antenna is very efficient. When I am mobile that is not possible, but fixed, I want an efficient antenna.

REG: Please consider this.

Most TV transmit antenna systems have an adjustable RF transformer installed at the antenna input connector. This transformer consists of 4 or 5 brass "pins" of about 5/8" diameter spread evenly across a 90 degree section of rigid transmission line. These pins can be inserted radially into the space between the outer and inner conductors of that line section. When the pins are withdrawn fully, they have no affect on the natural impedance of that line section, but can produce a spatially discrete SWR as function of their insertion distance into the line.

I, personally, and many other broadcast engineers have been involved in the adjustment of such RF transformers to optimize the match between the main transmission line and the antenna input [including its elbow complex(es)], at the frequencies used in commercial VHF/UHF television -- which start at 54 MHz.

This requires (1) purchase and installation of the transformer, (2) deployment of a tower crew to adjust it, and (3) use of a qualified field engineer in the tx bldg with the appropriate test equipment and field experience to direct the adjustment of that variable transformer.

Obviously, these processes are not inexpensive, and would not be undertaken if there was no reason. The reason: to optimize the match between the main line and the antenna, and thus to transmit the "cleanest" video.

This PRACTICAL experience illustrates that an impedance change even in a 54-60MHz TV channel occurring within a physical space of less than one inch can produce important and commercially supportable system benefits, despite your statements quoted above.

I invite you to post the contrary result(s) of your own "practical
experiments," and/or those of others.

Richard, WE just look at PL259's from somewhat different viewpoints and see
different magnitudes of the factors involved, with different objectives,
even different costs.

Connectors available off the shelf are not perfect, especially the pl259
type that are usually used by many.
While I don't doubt the problems to TV signals, this is an amateur group
type discussion.
Many antennas are nowhere near the 50 ohms that the cable is. Most any
connector will not cause any more problems than the coax/antenna mismatch
will in all but the most demanding systems (maybe EME or some satellite
work).

Out of curiosity, what other antenna provides a better cost-benefit
ratio while maintaining the same constraints with respect to power,
size, and construction?

Jack.

Sorry,

I've had a little accident while sporting and since I've only
a quick connection at the QRL, I couldn't check my mail and this newsgroup.

OK, thanx for the explanation. It seems I can leave it now! I thought it
would be a nice solution: a big amount of wire on a small area. But if
performance is even lower as other antennas and I can only come out on QRP
(I've got an FT-817) it is probably not the thing to choose for in first
instance.

Thanks all for the replies, links, etc. !!

RE: Clips from our previous posts (below) -

I don't know what constitutes a "serious disagreement" to you, Reg, but I think most readers would say that we have opposite conclusions about this topic.

If you have no reason to doubt what I wrote about this, how can you continue to support what you wrote? Our statements are mutually exclusive.

YOU: "Provided the mechanical connection is sound, you can use any coaxial connectors you like, regardless of nominal impedance, at frequencies less than about 300 MHz without any observed ill effects. A connector less than 1" long of impedance 51.5 ohms in a 50 ohm system will NOT produce an SWR of 1.03:1 or anything anywhere near to it at frequencies less than 1000 MHz."

ME: "This PRACTICAL experience illustrates that an impedance change even in a 54-60MHz TV channel occurring within a physical space of less than one inch can produce important and commercially supportable system benefits, despite your statements quoted above."

>> I want to construct a 5/8 wave ground plane for 24 MHz.

Wow, after all that, a simple answer. Thanks!

The reason I wanted to try 5/8 wave is because I have had
the Solarcon A99 1/2-wave ground plane for 10 meters up
for about 5 years, and it is an excellent antenna for DX. This
is, according to the product blurb, a "1/2 wave, voltage-fed"
design.

The radiation patterns in the antenna book give the
impression that 5/8 wave should be "even better" for DX.

Of course, a lot of that performance had to do with who is
on 10 meters in the first place, and conditions over the past
5 years as well.

It is finally falling apart (radials coming loose,) and the
prospects for 10m in the next few years don't look so good.
I wanted to switch to a similar antenna, but for 24 MHz.

I notice that some of the answers here were geared toward a
ground-mount, which is not what I meant by "ground plane,"
this antenna will be at 30', and probably will have full-size,
1/4 wave (?) sloping radials.

As it turns out, at the antenna forum in Dayton, Dean Straw,
the author of the ARRL antenna book, talked me out of using
5/8 wave. He feels that it will not appreciably enhance DX,
compared to 1/4 wave.

He also talked me into getting the latest version of the
antenna book, which alas, still does not mention doing what
you suggest, not even in the VHF section, as one person
mentioned, but at least I have the answer now. Thanks again.

Hello:

Thinking about replacing my present random-length antenna which I have strung around the 4 sides (open loop; 40x25x40x25 approx.) of my attic.

Do listening only. Receiver is grounded to a cold water pipe.

Want omni directional, and wide continual freq. coverage; few hundred KHz up to 30 MHz.

Is there an antenna I can purchase for my yard that would offer the "possibility" of significantly
improved reception ?

Don't want a tower, or something overly large that would take up my entire yard !

Thanks,
Bob

A good preamp (with FM, TV rejection) using your current antenna would work
as good or better that a larger antenna.

David, even for purposes of this discussion, that is a bit oversimplified. Perhaps that type of broadband temporary antenna installation is acceptable for field units, but have never seen one of them in a permanent installation. I happen to be around several hundred HF antenna installations, and neither NVIS nor ALE operating units use anything of the kind. Maybe you were referring to field units, as above, not sure. Also, ATU/couplers are always used for ALE systems, with the memory-response times measured in milliseconds. This applies to air, ground and marine units for all armed services. There is no magic antenna for all bands ALE, and units using NVIS would have little need for ALE in the first place. That doesn't mean the military hasn't wasted money on it somewhere for short range use, it just wouldn't realize it's potential for reliable medium to long range linking.

Larry D. wrote:
"The reason I wanted to try 5/8 wave is because I have had the Solarcon A 99 1/2 wave ground plane for 10 meters up for about 5 years and it is an excellent antenna for DX."

OK. A comparison of unattenuated field strengths at one mile from various verticals is given on page 20 of the "Vertical Antenna Handbook" by Capt. Paul H. Lee, USNR, K6TS:

1/4-wave, 196 mv/m

1/2-wave, 236 mv/m

5/8-wave, 276 mv/m

Power varies as the square of the voltage. One can see the difference in the field strength is hardly worth the effort for an amateur to try to increase the length of his antenna. It`s about a 3 dB gain from 1/4-wave to 5/8 wave.

A 5/8-wave at 10 meters is 1/2-wave at 12.5-meters (24 MHz).

A 1/2-wave at 10-meters is 0.4 wavelength at 12.5-meters (24 MHz). One could resonate it with a series capacitance at the antenna.

Best regards, Richard Harrison, KB5WZI

Depending on what you mean by "... few hundred KHz ...", a large,
indoor, tuneable, rotateable loop antenna may be a good augmentation
to your current, adequate "... random-length antenna ..."
This-a-way, you can rotate to maximize signal reception, or rotate
to minimize interference.

With a little additional "complexity", you might install such a
loop in the attic, as well.

My wife and I recently spent several weeks touring around Peru (just
got back last week).

I was intrigued to observe a _lot_ of modest-size HF wire antennas
scattered around... and these all appeared to be of this same basic
"terminated, folded dipole" variety. I saw a couple at the Cuzco
airport, one at a village on the Amazon, one or two in Aguas Calientes
(the village right below Machu Picchu), etc. They were usually
mounted in an inverted-V configuration, and appeared to be permanent
installations rather than short-term field-use installations.

The applications were probably NVIS, with working ranges out to a few
hundred miles.

I can't say for certain that they _were_ T2FDs, as I had no way to go
up on the towers and confirm that the device at the center of the
upper part of the dipole was a terminating resistor. I've never seen
a folded dipole with an open-circuiting insulator at the center of the
upper span, though.

My guess is that these antennas were chosen because of their "one size
fits all" nature - they can be installed and used without trimming,
don't require SWR-matching at the transmitter, and their relatively
low efficiency may not be an issue in these applications.

Richard,

A radio amateur, by an easy mistake, uses a 75-ohm plug and socket in a 50-ohm coaxial transmission system. The total length of the plug plus socket is 1"

As a result of the mismatch what is the SWR produced on the 50-ohm line at 2 MHz. At 30 MHz? At 150 MHz?

Is the amateur, or anyone else, likely to be aware of any difference in performance?

No need to make measurements. If you are unable to make a simple calculation and answer the question then you are not qualified to continue the discussion.

They conform to the manufacturer's specifications.

But the manufacturer's specifications do not mention, at least in numerical terms, the most important parameter - antenna GAIN.

The omission can mean only one thing - very poor gain at the lower frequencies.

But that is easily corrected by pumping in 10 Kwatts.

Hi,
Since much has been made of the pros and cons of the B&W dipole or T2FD, I thought it would be interesting to see if other amateurs have managed to homebrew one of these. The B&W costs $200 USD. Seems like one could make something that has the same amount of inefficiency for a lot less dollars. Maybe use resistance wire (nichrome?), or connect a light bulb at the feedpoint. The Isotron has been mentioned, but it costs too much. Any ideas?

But a trap needn't be any more self-resonant and lossy that a loading coil. A loading coil could function as both if it were in the proper position for the upper band(s). No?

Traps are a different subject. Self-resonant coils should only
be used at a current minimum point. IMO, they are much too lossy
to be used at a current maximum point.

LPs don't care!!

They are a driven array and fed from the shortest wavelength. So, as the active region becomes resonant the RF Power is radiated by the active region. The portion of the energy that 'sneaks by' the active region is negligible.

Check the Tennadyne site: <http://www.tennadyne.com> and the ARRL Antenna Handbook.

Good Idea, and we want to decrease efficiency, so the wind-up system may just may be what is needed. What I was looking for is antenna materials that decrease efficiency.
If we could come up with something as bad as the B&W dipole for a lot less money, then we may have something.

Try this: a 16 Ohm resistor in series with each side of the dipole, and a
100 Ohm resistor across the feedpoint. Unless I messed up, this will give
you SWR =< 2:1 for all conditions including shorted, and absent dipoles.

I'm not sure about "both". It's more than obvious that a resonant
coil+cap will (almost) always be more efficient than a self-resonant
coil.

Actually Dave, it is a problem in some LPDA's:-). The self scaling of the active region can degrade without a fix on some designs. Most commercial LPDA's, such as the itty bitty WLAN LPDA's, have an inductive via as a short to stop the back-resonance.

I'm sure they talk about this in one of the Antenna Compendiums. I can recall the discussion but not the volume.

Why stop there? A single Bird Termaline will guarantee a 1:1 SWR over a
1:100 frequency range.

But mine will actually radiate. Efficiency could easily be 33% for some
dipole lengths/frequency combinations.

Does make a big difference, no current at the top!
The wire ends there, so current must stop.
Most current typically near the bottom, and feed, but can be higher up
depending upon bands.
Perhaps he is addressing the degenerate cases of antenna very long, and
antenna too short?

David, even for purposes of this discussion, that is a bit oversimplified. Perhaps that type of broadband temporary antenna installation is acceptable for field units, but I never noticed one of them in a permanent (U.S.) installation. I happen to be around several hundred HF antenna installations, and neither NVIS nor ALE operating units use anything of the kind. Maybe you were referring to field units, as above, not sure. Also, ATU/couplers are always used for ALE systems, with the memory-response times measured in milliseconds. This applies to air, ground and marine units for all armed services. There is no magic antenna for all bands ALE, and units using NVIS would have little need for ALE. That doesn't
mean the military hasn't wasted money on it somewhere for short range use, it just wouldn't realize it's potential for reliable medium to long range linking.

Mike> feet.

I guess it depends on what you consider "adequate". If your 96-ft
dipole provides comparable SWR matches across all the bands the B&W
antennas allegedly provide, that'd be pretty impressive. Like the
other poster, I noticed that there were no gain figures in the B&W
literature, and that does make me suspicious.

Mike> My dipole cost less than 30 dollars to make. If you count the
Mike> tuner, I still spent less money.

Sure, so did I. And my antenna was messed up the following spring,
due to stretched wire, water leaking into critical bits, and more. If
you spent less than thirty dollars and used copperweld or stainless
steel, then I'd like to know what trucks that wire falls off so I can
chase them around town.

IMHO a trap behaves like a disconnection (high series impedance) at its resonant frequency, effectively shortening the antenna wire. It behaves as a loading coil at any lower frequency. For example a trapped 40 + 80 metres dipole is shorter than a full-size single-band 80 metres one due to the loading effect of the traps. The losses in a trap on LOWER THAN RESONANT frequencies are an issue, of course - the trap is placed off a minimum current point at these frequencies ! Maybe coax traps (e.g. http://members.shaw.ca/ve6yp/CoaxTrap.html) would be fine ?

The practical answer for amateurs is somewhere between the two extreme positions that Richard and Reg are taking.

Richard quotes a case where even very small impedance bumps do matter; but it's in full-quality TV broadcasting, not amateur radio.

Reg, on the other hand, wants to dumb it down too far. There *are* cases in amateur radio where small impedance bumps are at least noticeable.

At 2MHz or 30MHz, the effect is so small that no amateur would notice it. Even using professional test equipment, you'd be hard-pressed to measure the effect of a single connector of the wrong impedance.

At 150(144)MHz, even a single connector is noticeable... but that's not the problem.

The real problem is that if people believe a simple slogan like "connector impedances don't matter", they will probably go ahead and use *several* mismatched connectors, at various places along the line.

Then they start to find bewildering problems at 144MHz and above, such as indicated SWR and power output values that vary according to the length of the coax jumpers that they use. It still may not matter in terms of the contacts they can make, but they are completely unable to understand what is happening - and that *does* matter!

(What is happening, by the way, is that the lengths of the line sections between the mismatched connectors will determine how the small reflections from each one combine together. If you're lucky with the line lengths, they may tend to cancel; if you're not, they may tend to add... and usually it's somewhere in between.)

>No need to make measurements.

In this particular case, that's true. When the impedance bump is small,
it is easier and more accurate to calculate the effect than to measure
it.

Some years ago experiments have be done using trees as antennas. Where
can I find references about ? Do fellows here known about the results ?

I bet that includes a large capacity hat though. If he is using a large hat, what he says is true. If he is not using a hat, it is not true. And I'm sure he knows that. Any current taper through the coil in itself, has little bearing on the best location of the coil and performance. Taper, or no taper, it's location will greatly effect efficiency when NO hat is used. No doubt about it. But, if you are using a large hat, what he says is fairly true. The location of the coil really doesn't matter near as much, because the current distribution is fairly linear even with the coil at the base, middle or top. There might be slight improvements by raising the coil on a large hatted system, but it will be minor compared to the no-hat version. MK

Dunno. My real world tests don't quite agree. In using 30 mile ground
wave tests across town, I tested 1/4 GP's, 1/2 waves including
decoupling sections, and a 5/8 GP with 3/4 wave radials. All at 36 ft.
The 5/8 ate the 1/4 GP for lunch. Probably 2 plus S units better than
the 1/4 GP. The 5/8 beat the 1/2 wave by 1.5 S units. And this was
tested and repeated over a period of months. Never varied. Ground wave
testing is quite stable, and accurate for those low angles involved.
Much more accurate than trying to compare using constantly varying
skywaves. In real world gains, thats more than 1 db. 5/8 antennas are
weird animals. On 2m, they suck. On HF, they can do fairly well, cuz
the angles involved are not as critical. I used a 5/8 GP on 17m for
2-3 years. "also at 36 ft at the base".
It mangled every other antenna I had on that band. On 10m, the 5/8
beat any other length radiator quite handily. Again, on the critical
2m band, peeeyooooo.....they stink. BTW, on skywave, using a quick A/B
test, all preferred the 5/8, over the other antennas. So it wasn't a
low angle ground wave fluke. MK

Then howcum my 5/8 wave mag mount 2m mobile antenna very significantly
outperforms the 1/4 wave mag mount antenna I used to use? Same ground
condx, same power, same feeder length, same vehicle, etc. I suspect
it's in the differences in the TO angles.

they are fractal, I think someone might sue you for infringement. :)

2333. Re: F-connectors

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-18 13:59:19 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <c8d4rngqh1@hercules.btinternet.com>
Source record: 95086

Let's do what nobody has ever done before, not even in the ARRL handbooks or in Terman, and get an idea of the magnitudes involved.

Examine two cases over a range of frequencies.

Case (1). In a 50-ohm system, use of a poor connector having an impedance deviating 10 percent from its nominal value of 50 ohms.

Case (2). Making the mistake of using a 75-ohm connector in a 50-ohm system.

In both cases the connector, plug and socket, is 1" (25.4mm) long.

We first calculate the input impedance of a 75-ohm transmission line, 1" long, terminated with 50 ohms. Zin will not be very much different from 50 ohms.

We then calculate the SWR on a 50-ohm line which is terminated by the afore-mentioned input impedance.

RESULTS of calculation

MHz	SWR Case 1	SWR Case 2
2	1.0002	1.0009
30	1.0028	1.0146
150	1.014	1.073
300	1.029	1.145
1000	1.105	1.524

It is seen that results do not become significant to a radio amateur, and almost everybody else, until he has made the serious mistake of using the wrong impedance connector, and the frequency has risen to 1000 MHz for which he hasn't an SWR meter anyway.

Below 300 MHz the results are submerged well beneath the uncertainty of an SWR meter. Now we can take a balanced view of the situation.

Reg,

I suspect your 1 inch length is overly pessimistic. Clearly, for an F connector, it is more like 1/2 inch. Lastly, if the load at the end is not 50.0, then any small deviation in the feedline could just as well improve things, as make it worse; this is probably not true for pulses or video. Think of an antenna tuner. It does nothing to the SWR on the main piece of line.

Source record: 95088

Been there, done that, many times. If the vertical is
a half wave, you can just use the shield of the coax
feeding it as the little bit of counterpoise you need.
In direct A/B comparisons to quarter wave verticals
over good ground screens, the no ground vertical
half wave is so close in performance you can't measure
the difference.

Coil loss is not an issue if you use the proper coil.

I didn't do a great engineering job on my first 50' mast, just one of 5 I will be eventually putting up for a loop skywire. Now I will have to take this one down and do it right (big headache). Anyone know a good source (good prices), for those high quality nautical type pulleys? What is best type of wire for guys?

Meanwhile I did finally get on the air with my 80M OCF up 35', got over some initial mic shyness, and hopefully will go back for more, after I brush up on not sounding like a lid.

>>Yes; I knew when I made rocks and trees into antennas I was going to get
>>some flack.
which served ego rather more than technical discussion.

This thread still remains as one of the most comic pieces published in
this group and worth reading the 59 entries. Where the comedy lapses
into technical content (rare), it provides specific information about
plants and RF interaction. I am glad to have run into specific
conductivities comparisons showing how the vaunted "conductivity" of
sea water is 200000 times worse than nichrome (or 10000000 times worse
than copper).

This one was not the only thread confined to this topic, but I would
wager all the rest amount to tedious repetition of the usual
population count of angels on a pin-head.

By hearsay and legend -- In W W 1, an Army Field manual recommended feeding
a tree for an antenna when the real antennas were shot down.

Since I am not aware of any 50 ohm trees (hi-hi), probably use ladder line
and a tuner.

And remember, as an old timer discovered when he loaded his bed springs ---
RF GOTTA GO SOMEWHERE

Let us know which trees worked best (:-)

Reg,

Your math example does not illustrate the >> reality << that the impedance change produced by a ~5/8" OD brass pin inserted radially into the dielectric space of coaxial transmission line can match that line into an adjacent termination of fairly high SWR (1.3:1 or so), at frequencies as low as 54MHz.

As I wrote earlier, this technique is widely and successfully used to match the main transmission line of broadcast TV and FM stations to the net input impedance of their antenna (including its input elbows).

Well -- I have found that modelling gets you in the ball park (an
approximation)
A good SWR meter will allow you to tweak it up.

For 1/4 wave vs 5/8 wave 2M antennas -- I have found empirically -- that
when in an area surriunded by big mountain tops -- like Silicon Valley in
the CA Bay area -- the 1/4 wave works better due to its higher angle of
radiation of the 1/4 wave

When on the open road where terrain is flat and the mountains are far
away -- the 5/8 wave works best -- lower angle of radiation.

This is just my empirical observation --- your radiation angle may vary --
hi hi.

This is strange: The contact email address for this company includes the
callsign of the person who posted this link claiming to have purchased
one of these oh-so-wonderful antennas.

What a compelling unsolicited testimonial!

Alan AB2OS

On 05/18/04 12:10 pm vk3kcg put fingers to keyboard and launched the

No majik there, they work about as well as you would expect an antenna
that size to work. That is, not very well. They look cool though!

> literature, and that does make me suspicious.

Right, the two antennas are not quite comparable. I have to use a tuner
on my antenna. But that really isn't a handicap IMO. I contest with my
rig, and although I have to be careful on 80 meters, I can change bands
and set the knobs to their proper positions in just a couple seconds.

> Mike> My dipole cost less than 30 dollars to make. If you count the

> due to stretched wire, water leaking into critical bits, and more. If
> you spent less than thirty dollars and used copperweld or stainless
> steel, then I'd like to know what trucks that wire falls off so I can
> chase them around town.

Never used copperweld, except for twinlead. You can get it pretty
easily though.

The trick with regular copper is to pre-stretch it. You get a helper or
two on each end, and give a good steady pull to stretch it.

And yeah, Mother Nature can be a b***h sometimes. My dipole has been up
over 2 years now, and is still surviving. That is probably as much luck
as my construction genius! 8^) I'll be taking it down for some
modifications - I'm going to lengthen it so I can tune 80 meters better,
so I'll see soon how the plastic parts held up.

I think what I am driving at here is that everything comes at a price,
some monetary, some functional. Antennas like the B&W FD are great if
you want minimal fuss. That comes at a price in performance though. I
went real cheap. The price I pay is using a tuner. That doesn't bother
me at all - I'm an inveterate knob twiddler!

I recently bought several toroids, and unfortunately, one of them dropped and broke in half.

Is it possible to super glue the thing back together? It's a clean break.

I was figuring that since toroid coils are often stacked, it would be similar in effect.

Strange sound, not heterodynes. SSB can do some funny stuff demodulating a
shifting (other type of) modulated carrior.

Hi OM,

There is modeling, and then there are modelers. 99.9% of errors are found with the second. A simple example that explains the illusion of disparity may be tested with the free version of EZNEC (as is generally the case).

Model a ground plane antenna at ground level (or simply an inch or cm above it); and then raise the same antenna a quarter wave (not so difficult to manage at these breathless reports from VHF-land).

Difference approaches 6dB for this trivial exercise alone. Models answer the differences quite well, modelers can be found in commercials wearing lab coats saying "I'm not a doctor, but...."

No, that is impossible, John, as it would be against the rules of this user group. The only possible explanation is that VK3KCG fell in love with this magic radiator so much that he simply had to buy the company. Of course, this purchase happened BETWEEN his testimonial and when Alan saw his callsign on the web site.

A little simple deductive reasoning solved the problem.

My point exactly. Hence the previous rule of thumb
stated two different ways.

1. Don't use a 75m loading coil while operating on
higher frequencies.

2. Don't use a low-pass filter on *operating* frequencies
above its passband.

Strange, every measured experiment he himself conducted on real-world
air-core coils proved that the current at each end of the coil is NOT
constant.

Did he say if one puts the loading coil at the top of the antenna,
with no stinger, currents at the top of the coil and bottom of the
coil are equal?

When will otherwise rational engineers stop trying to use circuit
model math on distributed network problems? The current in a standing-
wave antenna wire is NOT constant, varies inch by inch, and that's a
straight piece of wire. So if we use more wire coiled up, the current
then becomes constant magnitude/phase and instantaneous? (faster than
light?) To speed up computer buses all we have to do is install coils
in series?

Did you notice W8JI changed his web page? The once outrageous statements
have been considerably modified.

Richard> Hi Jack,

Richard> This is still inspecific. "Full height" is actually
Richard> meaningless. Let's look at a 40M dipole antenna and choose a
Richard> modest 20° launch angle to compare against. 5M over real
Richard> ground: -2dBi 10M over real ground: 1.29dBi 15M over real
Richard> ground: 3.75dBi 20M over real ground: 6.27dBi 25M over real
Richard> ground: 8.08dBi 30M over real ground: 7.67dBi 35M over real
Richard> ground: 7.1dBi 40M over real ground: 7.52dBi

Where did the twenty-degree launch angle come from?

Richard> Well, let's see - best gain is NOT at any cardinal point such
Richard> as quarter wave, half wave, three quarter, nor full wave
Richard> above ground ANY of which "could" be interpreted as "full
Richard> height."

I'm not familiar with twenty-degrees as any particular canonical
value. As for what I meant by "full height", one-quarter wavelength
minimum should serve.

Richard> This exercise is easily within the limited feature set of the
Richard> free distribution of EZNEC.

I do not doubt that your calculations are within the capabilities of
EZNEC. However, I'm more interested in real-life experience, not
computer-generated simulations.

EZNEC will probably give you a better idea of whats going on than anecdotal
opinions. There of course is always the GiGo factor but this applies to both

computer and human analysis alike.

Depending on how much longer your antenna will be, you may notice a modest improvement in signal strengths on the lowest frequency band. But you might notice a small decrease in signal strengths on the highest frequency band. On the other hand, you may notice nothing at all except a change in tuner settings. But a change in tuner settings can be beneficial.

I would prefer a Z or C shape. This maintains a high average height for the antenna and so increases the probabilty of improvement in signal strengths.

The directions in which the ends are extended will have a slight effect on radiation patterns which you will NOT be aware of. As your dipole is non-rotatable it won't matter anyway. For practical purposes, taking one band with another, you can still refer your antenna as being omni-directional.

Reciprocity ensures whatever happens on receive will apply equally to transmit.

Wait a minute here... Seems to me that Reg is talking about two opposing steps separated by a very short distance, and Richard is talking about a single step from one impedance to another. Clearly, Richard's case results in uncancelled echos related to the ratio of the impedances at the step. In fact, Reg's example results in significant uncancelled echos if the steps are separated by enough distance: worst at odd multiples of pi/2 electrical degrees. When the connector is only perhaps a few electrical degrees long, the steps nearly cancel. How long is 1", in electrical degrees? Well, at 1000MHz and a v.f. of perhaps 0.7, longer than one might have anticipated: almost 45 degrees long. So in fact at 1000MHz, a 1" section of 51.5 ohm connector might introduce a bit more than 1.03:1 SWR. But didn't we start out talking about a much lower frequency, and a much larger impedance difference? Another example I ran was 4 electrical degrees of connector...perhaps a bit less than an inch at 150MHz...where it's 75 ohms in a 50 ohm system. The swr for that came out about 1.06:1.

The TV broadcast engineer should worry about things like that. The typical ham doesn't have equipment calibrated accurately enough that s/he should be worried about it, and it's unlikely to make any substantive difference anyway in typical ham work.

Cheers,
Tom

Agreed.

> plays a major part in performance.

No surprise there although my instincts tell me that once some number
of "critical" square feet of vehicle sheet metal is "achieved" the
size of the vehicle has a less pronounced effect particulary at VHF
and UHF freqs. But modeling has the annoying ability to deflate
instincts.

> I also noted, on the average, the 5/8 produce a slight gain over all,

> mounted on.

That would easily explain my offhand experiences. In fact I did it
again last weekend. An buddy of mine is temporarily laid up in a
skilled care facility so I got his home 2M FM station running in his
room. I installed his 1/4 wave magmount whip on one of those typical
steel-shrouded HVAC units often found under the windows of patient
rooms. He couldn't hit the repeater. I went back later and installed
my 5/8 wave whip and yup, now he can hit the repeater.

Because 99.99 percent of models are never properly tested in practice and in an anateur's back yard, if they WERE tested, the radiation patterns would only bear a vague resemblance to predictions.

Predictions are mostly wishful thinking. Nevertheless, they can be a satisfying intellectual activity.

Reg.

Yeah, kudzu could have some advantages. Lots of it available, and
you'd probably end up with a dense-fractal design.

It'd have the disadvantage of de-tuning itself every day or so, due to
the rapid growth, unless you transmit with enough power to burn off
the growing tips. Lends a new meaning to "pruning your antenna".

The three rules of growing kudzu:

- Although it's capable of growing on solid concrete, it'll do
somewhat better if there's at least a little soil in the mix.

- Always plant kudzu at night, by the dark of the moon. Otherwise,
your neighbors might figure out what you're doing, and start
throwing rocks at you.

- Fertilization is not required. However, the kutzu vines will
definitely appreciate having the bottoms of the smaller leaves
lubricated with 10W40 motor oil - this reduces abrasion and chafing
when the vines grow rapidly across the ground.

[Taken from an old Whole Earth Catalog]

Or more precisely, the amplitude of the mathematical superposition of
forward and reverse traveling wave currents in a half-wave dipole
antenna varies inch by inch.
It is the EM fields produced by the traveling wave currents that in fact
superpose. That superposition results in a net field which is identical
to the field which would be produced if a 'standing wave current' could
in fact radiate.

That is the main thing I am trying to do. The tuning is pretty sharp on 80-75 meters. (the dipole is 96 feet at present) It works okay, but since I am going to experiment with higher powers, it seemed like a more forgiving tuner environment might be a big plus. Plus of course not having to use as much inductance.

Of course, I was referring to *net* current which is a superposition
of forward and reflected currents, or H-fields if you prefer. The bottom
line is that if magnitude and phase vary inch by inch in a straight piece
of wire used in a standing-wave antenna, are we to believe that the variation
can be reduced by adding more wire, just in a spiral?

My web page problem is the definition of the reflection coefficient.
RHO and S11 have different definitions. Stand by for an explanation that
even you can understand. :-)

Mike> twiddler!

I wholeheartedly agree. There's a price to be paid for every setup --
if you're not paying out of your wallet, you're paying out of your
time, or out of your loss of capabilities. It's one of those basic
facts of life. I also went dollar-cheap, and I'm getting what I pay
for. I'm considering going for something like the B&W for my next
location should it be appropriate, to see if I can get my money's
worth out of it. Worst case, it ends up getting sold second-hand on
eBay. Best case, well, we can all dream. :-)

Below is my response to an off-list e-mail I received on this topic, which to some readers may add additional perspective on this topic.

RF

Visit http://rfry.org for FM broadcast RF system papers.

Thanks for your comments.

The reason I chimed in originally was because of Reg's absolute statement that preserving system Z throughout the transmission line and its connectors was unimportant below 1GHz (later 300MHz?). He said further that an impedance change across a 1" length of transmission line was irrelevant in that same spectrum.

That is demonstrably untrue, as I pointed out by a real-world example taken from the broadcast industry.

The net terminating Z of a TV/FM transmit antenna with its input elbows usually is not exactly 50 ohms, even though that is the impedance value that the hardware was designed to provide. Manufacturing, assembly and installation issues can and do change it. The main transmission line normally is closer to 50 ohms across the relevant bandwidth than the antenna/elbow termination connected to the far end of that line.

The Z-matching hardware I described is effective at optimizing this far-end match, it _does_ improve the quality of the radiated signal, and it minimizes the stress on the main transmission line and the transmitter. And it does so by changing the impedance in a 1" or less length of transmission line adjacent to the antenna input, regardless of Reg's beliefs.

Hams operating on the HF bands may not wish or even need to consider this, as I mentioned in an earlier post to this thread. But that is not license for Reg or anyone else to write that such disregard is universally justified.

If you feed it with fertilizers containing lots of metallic elements, you should end up with a tall metallic pole with built in radials (the roots). You should be able to gamma match it by placing a metallic spike at the appropriate height.
You can trim the branches, however leaving them in place should provide a great deal more bandwidth. When you move, just cut down the tree, but save a few cuttings so that you can grow an antenna farm at the new location. With careful spacing, you might be able to produce some great arrays. I don't know about feeding them with open wire line, but surely Cecil with find a way. You might even be able to sell some of the antenna cuttings on e-bay!

Hi Mike,

The trick is to keep any gaps small. However, if I recall my magnetics right, an air gap, although lowering the magnetic properties (smaller inductance), also extends them (greater dynamic range, harder to saturate). This is the principle behind a "swinging choke." This, however, is not to say that it would offer any benefit to your application. The reason I say this is because ferrites we use for line chokes do not typically support enough flux to saturate in the first place (or if they do, you have one hell of a problem); rather, the ferrite characteristic of bulk resistance is employed and inductance is a fairly trivial side benefit.

What sort of toroids? If they're powdered iron, it should be no
problem. If they are relatively low mu ferrite, it should be a minor
problem at worst if you keep the glue line thin. If they are mu=6000
toroids, then a thousandth of an inch gap in an inch long path is
quite significant. If you relieved stresses, the break may not fit
back together with "zero" gap; it's something to check. A gap isn't
necessarily bad, just something to consider. In fact, gapped cores
can store more energy than ungapped.

Cheers,
Tom

==================================

Danny, there's nothing wrong with antenna pattern-prediction progams. There are good nunber-crunched side effects. It's only their practical application by people in their own back yards which is unreliable. It cannot be helped. It's a fact of life. The environment and performance of an antenna cannot be accurately predicted unless it is at a height of several wavelengths above and away from obstructions.

Not a single one of my programs predicts a radiation pattern. Only an exceedingly few professional antenna design engineers would ever make real use of such facilities even if I could write them. I don't like wasting time. I havn't all that amount of time anyway. Nobody has produced a new type of antenna for many decades. (Not even Fractal). It's all been done before.

But, as I say, radiation prediction programs are entertaining, educational and satisfying. Enjoy them while you can.

Nevertheless, unreliable is a fair practical description.

A QUOTATION:

"When you can measure what you are speaking about and express it in numbers you know something about it. But when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind. It may be the beginning of knowledge but you have scarcely in your thoughts advanced to the state of science."

: William Thomson, Lord Kelvin, 1824-1907.

Think in terms of magnitudes and frequency of occurrence of the effects. One 1" brass slug in a TV transmitting station, even if the subject of a learned paper, is surely of less consequence than millions of amateur and other SWR meters.

Beware of unnecessarily frightening amateurs by inadvertently exaggerating the importance of SWR due to ordinary variation in connector plugs and sockets.

Seems like I remember an article in the 70's in 73 magazine (what else?)
about this very subject. I don't have time to look back thru my old mags., but
I bet the results indicated trees don't work well as antennas. If they did, a
lot more hams would be using them. I don't think I have ever had a contact
with someone using a tree.

Oh come on!

Everyone knows that Al Gore invented the dummy load right before he invented the Internet! ;-)

>--
>73, Cecil http://www.qsl.net/w5dxp
>

No, but I will have a look. I have saved the "before" pages, so it will be interesting to compare. This would be typical of him. First ho goes quiet for a while, then he changes his beliefs, then he emerges as a guru, teaching the stupid about the virtues of his "inventions" (stolen, plagiarized from others.)

When I brought this to attention of K3LR, antenna forum moderator, he countered with "he wins contests and works DX"
and N6BV: "he is right". So I was grounded and dummyfounded :-)

Now that snow melted and I got my Radiomobile's brake lines fixed, I should do the experiments and get some real data and do that article. Just that I got sucked to another project, designing "Dream Radio" that I am more excited, especially after seeing pieces of (radio) furniture by the JA biggies.

I am sorry I missed W7EL booth, would have loved to say HI in person. Just gotta order the upgrade to EZNEC, I can use the new insulated wire modeling feature.

Maybe we can open a new branch of science, and solve some knotty problems.

Please, don't say "What a sap!". This is serious: we've got a trunkful of knowledge here in the group, and we can put the crown on this whole idea.

I'm not just barking at the moon.

>
========================

Mike, because you have a random length dipole you already have an idea of the relative importance of tuner settings. Increasing antenna length nearly always improves tuner efficiency on the lowest frequency band which, very often, is the most used band of an antenna.

Don't concern yourself unduly with actual value of tuner roller inductance. The main problem on the 160m and 80m bands is whether there's enough of it. If you wish to adjust antenna length to any particular value make sure its tunable with whatever the maximum tuner inductance happens to be.

Adjusting length of the transmission line can also be of great help.

I mention this hopefully for the benefit of less-experienced readers.

You are only sort of correct.

At HF where the local world is as large as your antenna, that statement is true, at 6m it starts to become less of an issue as the outside world becomes big and somewhat ignorable. At 2m it is quite ignorable, and at 70cm it pretty much isn't there. Yagis I have designed for 432 perform exactly as predicted by the software, with the exception of the ones too long for the antenna range, where the only discrepency was the gain tests a bit lower than the model predicts. And then it was .3 dB on an 18.4 dBd prediction.

It is possible to predict antenna gain and pattern very accurately if you do it at a frequency that does not interact with the local environment to a any large degree. It is also possible to build those antennas and have them perform the same time and time again. I've built dozens of long boom yagis for 2, 222, and 432, and after the first one, you don't even have to measure the SWR before setting the T match shorts unless you are anal or an EME're. Oops, same thing, I guess. ;) And every antenna I've ever range tested (thank you Central States VHF) has been within .1 dB of predicted except one.

The designs I have built over the last 15 years didn't need to be adjusted at all from the model plus predicted boom corrections. The only variable was the matching system on the driven element, which none of the modeling programs handles very well.

And for you picky folks, yes, the losses from foliage, etc. aren't ignorable, but the antenna system still performs as predicted unless you mount it in the center of a tree.

And I do realize I'm preaching to the non-choir here, since this group is (apparently) not very interested in anything above 10m. :)

Hi Richard,

Isn't it the other way around? If I recall a swinging choke does not
have a gap, which allows it to saturate sooner, changing the
inductance. A regular choke does have a gap. Speaking of stacked iron
plate type.

Gore didn't invent the Internet, but as a congressman, he did pass
bills that provided large amounts of federal funding for the
communications system that later came to be called the Internet. We
might not have an "Internet" without Gore.

Many thanks for all the responses.

I remember that in the experiment I have mentioned, the coupling to the tree was via an toroidal coil which was mounted around the tree, the tree beeing in the axis.

Sure, a tree cannot be a good antenna. Any "real" antenna will probably always be better. But often the question is: no antenna at all or anything which does not seem to be an antenna. Perhaps a tree can be such a thing. Further, in portable operation, it is not always easy to install a "real" antenna.

Probably fed, the coil loss is very low. The version I prefer is a
single turn coil, and a coax capacitor if needed. Very low coil
losses. I've used loads of the base fed half waves. Also have used a
center fed 1/2 wave. Never could notice any real difference between
the two in performance. The only advantage to a center fed I could
see, is possible use on other bands using a tuner. Many people do this
with the center fed 1/2 wave A-99 CB antennas. Trying to work multi
bands with a base fed antenna is not going to work very well. But I
don't recommend that anyway... MK

Source record: 95059

I regret I cannot give you an exzact reference but the WIA
magazine Amateur Radio, some years ago had such an article
and the results thereof. It worked quite well for what it was (a tree)
and there were even suggestions as to which species were better than
others! AFAIK it wasn't an April edition.

Some of the gum trees here are 150+ feet high and the trick seemed to
be tapping in at the right level from the ground.

Some unhelpfull folk later suggested the 8' of coax to the matching
network was the radiator :-(

I have no way of finding this info - maybe you can search the net?

Cheers

I am looking to put up either a 75 meter Horizontal loop fed with 450 ohm ladder line or a 40 meter Half Square. I would only be able to get either antenna up less than 40 feet. I have had the loop up in the past and it was a great preformer even at low heights.

Looking for antenna that would allow me to work into Europe as well as better signal to West Coast.

Would appreciate your thoughts and any websites that you know of that detail out a Half Square.

Thanks,
Scott

Trees are, as already noted, usable as VHF antennas when properly 'fed'...whether you should or shouldn't use a tree is your decision. It is hardly a new idea. Certainly placing a bona fide VHF antenna--in the clear--on top of the tree is the better of the two options.

The interesting question is: how does a tree compare to a ground-based monopole?

There is a reason why VHF monopole antennas are not on the ground, whereas MF ones are.

Experiment for more info. Many have been down this path before. I don't know a sap or a chump in the bunch.

John,

Call the MFJ factory customer service and order the DC motor. It's easy. I did it and the price is fair.

http://www.mfjenterprises.com/index.php

It can be useful to also replace the 2 microswitches near the DC motor. They are cheap when you order them together with the DC motor and they get also influenced by weather conditions and might need to be replaced soon.

Source record: 95064

Jack Twilley wrote:
"This is the kind of experience I had hoped to hear."

A look at the vertical radiation patterns of half-wave horizontals broadside to the antenna wire such as that shown on page 3-11 of the 19th edition of the ARRL Antenna Book provides evidence of the best height.

A vertical angle of 50-degrees gives a first reflection target distance of 80 to 500 miles, depending on the height of the reflecting layer, from the graph on page 92 of Ed Laport`s "Antenna Engineering". A vertical angle of 5-degrees gives a target distance of 700 to 2500 miles according to the same graph.

For angles between 5 and 50-degrees, a dipole height of 1/2-wave maximizes radiation around a vertical angle of about 30-degrees.

Hi David,

It may take a little more adjustment to tune, but that should be the
only down-side. You should at least tune it at 8 feet (or similar,
convenient height) first to confirm its construction.

A well made G5RV, for one. A well-made W3DZZ trap dipole, for another.
W5DXP's "linear tuner" dipole, for a third. Or the classic
dipole-with-openline-and-a-real-balanced-tuner for a fourth. All are
much more efficient than a T2FD of the same size.

The B&W/T2FD is discussed in detail on W4RNL's excellent site (which
see). In short, its efficiency is quite low on the lower bands and
gets to be almost as good as a halfwave dipole on the upper bands.
Their one and only advantage is low SWR over the frequency range.

Hi,

I used one.
At ground level it needs many flexible radials burried into the ground to
give good results.
Then I placed it on top of a small tower 10m high without its flexible
radials, the result is much better.
I remember than R1ANF was on 20m, I call him in SSB only a few seconds
using my TX barefoot, and I had my QSL !
This is not a proof that the R7 works well, but in all cases, there is
nothing to tell against it. This is probably one of the best vertical on the
place.
But try to place it in height, that will improve the radiation pattern.

I have a "T" antenna tuner (two capacitors on each side of the roller coil). The coil goes to ground.
Should I adjust for maximum inductance (farthest from ground) or minimum inductance (closest to ground) on the inductor? It tunes well on both ends of the coil.
I don't want to pump it full of watts and see it smoke.

Thanks in advance, Scott

Source record: 94922

Au Contraire -- this is NOT a quarter wave vertical -- it is a half wave end fed antenna and if you read the Cushcraft manual it explicitly states "The R7 should not be attached to a ground radial system". The feed point is a high impedance point and the black box matches the 50-Ohm coax to this high impedance - thus no radials are required -- in fact adding radials will screw up the antenna.

As for height -- mine is 8 feet off the ground and works very well. A friend had one up about 25 feet and we got very nearly the same reports in on the air checks. BUT -- there are a lot of variables in all this -- ground conductivity, obstructions, terrain, etc -- so mounting higher MAY give better results -- I know users who found this to be true at their location.

BUT if increasing height will help clear obstructions -- then by all means mount it up higher.

The flexible rods at the bottom of the antenna are according to Cushcraft "Counterpoises" to isolate the antenna from ground. They are not long enough to be resonant radials on any band.

Before doing anything -- READ THE MANUAL!

Read the manual -- it should specify this, my old tuner manual says:

"Always use the lowest possible value of inductance that will give a proper
match. Using higher inductance can result in wasted power inside the tuner,
and may cause damage."

Your tuning may vary -- let the reader beware

I always used radials when using ANY vertical at ground level successfully,
whatever write manuals.
I laways use counterpoise when erected in heights, and in both cases,
results are there.

Well Thierry your advice is good for a 1/4 wave vertical -- but not a half wave end vertical.

Lookup the theory and you will see why.

Well Thierry -- your advice is good for a 1/4 wave vertical -- but not a
half
wave end-fed vertical.

Look at the theory and you will see why.

2424. Tri-Ex HS471 instructions?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-19 23:54:51 UTC
From: James Horn <jimhorn@svn.net>
Message-ID: <10ansubirredr7f@corp.supernews.com>
Source record: 94935
Cross-posted to: rec.radio.amateur.equipment,rec.radio.amateur.antenna

Does anyone have the instructions or manual for the Tri-Ex HS471 avaiable?
I'd like to get a copy if possible. *Many thanks*!

Jim Horn, WB9SYN/6

Hi Dave, here is my 2 cents worth on the R-7. Purchased it second hand last summer, had to fix it due to high SWR on all band except 10 meters. After checking out antenna did find that the 12 meter trap was the problem, and after fixing it , well it was time to mount it. The installation here is 12 feet about ground , mounted on the baby barn, nice and easy to work on it from the roof of baby barn. Also did put 3 guy wires just under the 10 meter trap. Antenna is performing a lot better than expected on dx and is holding its own on 40 meters local and roughly 600 miles during the day, of course all depends on probagation also. But i am extremly satisfied with the antenna so far, and with guys on it, well, dont have to worry much about it during strong winds, as they do have a tendancy to bend a bit. It is also in close proximities to trees and stuff, but does not seem to bother the antenna pattern at all and swr is what the book says.
this is my 2 cents worth.
thanks for reading.

Don't know the "best" height, but usta live next door to a guy with an
R7, and he mounted it at about 30 feet. It performed fine, as far as
he was concerned. Main downside to the antenna is a fairly narrow
tuning range on 40 meters.

There is absolutely nothing wrong with Thierry's advise. As the
subject of radials/counterpoise/ground is often either over engineered
or under engineered (often to no apparent difference to the distant
contact). It may complicate the tune, but it may also bring reward.

>Lookup the theory and you will see why.
>
>http://www.njqrp.org/n2cxantennas/halfer/

Hi OM,

If someone wants to invest in the treatment that Thierry suggests,
there is no down-side - this "theory" notwithstanding (which, by the
way makes no effort to prohibit it, to its credit). Multiple radials
also serve to decouple the feed line which then provides a more robust
reference against which the antenna operates.

==========

A terminated rhombic does NOT have a loss in the forward direction.
Radiation in the forward direction remains the same as when unterminated.

When terminated it is radiation in the UNWANTED reverse direction which is
absorbed by the termination and suppressed.

N2EY> size.

The only one of those I haven't seen is the "linear tuner" dipole.

N2EY> The B&W/T2FD is discussed in detail on W4RNL's excellent site
N2EY> (which see). In short, its efficiency is quite low on the lower
N2EY> bands and gets to be almost as good as a halfwave dipole on the
N2EY> upper bands. Their one and only advantage is low SWR over the
N2EY> frequency range.

I've looked, but the T2FD that's discussed isn't the one I'd be
buying, and I'm not sure if that matters.

I've seen advertising in QRT for the latest new miracle sticks:

SAPSUCKER 2000Tï¿½.

and the mighty:

BARKBURNER 9000TRX-DXï¿½

Note that the ground qualities will enhance automatically by using
such an treetenna. That is because most all dogs will stop and urinate
against the base of said device. Add a few beer drinking buddies to
the party, and you will be a dx chipper in no time. Squirrels can add
nests, which will act as additional top loading.
Beware of tree beetles, infections, etc.. After a while the treetenna
could become a:
STUMPSTICK
Gasp!
These have been proven to be inferior radiators due to the *stumphole
effect* to the rf as it encounters the many rings in the tree stump.
These proceed to turn the rf round and round ,like flushing a toilet,
and ploink, you blow the finals in your rig, due to a massive
wormwood pulse that flows back along your feeder to the rig and your
operating position. Usually a desk or table made of wood, which
further increases the potential of damage to the station.

Just remember that a half-square is a bi-directional antenna
and would need to be rotated to cover both the West Coast
and Europe with its highest gain. If you aimed the half-square
toward Europe, the other major lobe would be aimed at Southern
Mexico. If you aimed it toward Los Angeles, the other major lobe
would be aimed at West Africa.

I dialed up 10.512 MHz a couple of nights ago. I began to belive that this posting was someone's idea of a joke, as all I heard was some Spanish-speaking stations talking back and forth,like many of them do on what they think are "private and unused by anyone else frequencies". The next day, I heard the "music" - it wasn't too strong here in the Pacific NW about 5:00 PM PDST Local time, and weaker yet at 11:00 PM. I couldn't hear it at all early this morning (6:00 AM).

Very interesting!

2443. Re: Cushcraft R7

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-20 15:14:18 UTC
From: Just Another Opinion <JAO@somewhere.net>
Message-ID: <eX3rc.811$zE6.12@lakeread06>
Source record: 94945

Richard, Thierry and the original poster I repeat:

The R7 is NOT a quarter wave vertical -- it is a half wave end
fed antenna.

A quarter wave radiator needs a ground plane or radials to work against for
sure -- but Cushcraft sez a half wave antenna doesn't need radials as it is
like a horizontal dipole turned vertical and end fed (high impedance) rather
than center fed.

I suggest you read and study the following:

The Cushcraft manual it explicitly states "The
R7 should not be attached to a ground radial system".
URL: http://www.cushcraft.com/support/pdf/r7.pdf

Do you know what is in the black box matching unit ?? If not see URL:
http://www.iol.ie/~bravo/r7_vertical.htm

A local Ham added radials -- couldn't tune the antenna -- so he added a
tuner. When he ran a kilowatt into this mishmash -- the black box blew up.
So he repaired it as in URL:
http://www.iol.ie/~bravo/r7_vertical.htm

He no longer has the added radials and tuner and runs a KW all the time with
no ill effects -- let the experimenter beware.

I know this is a controversial subject -- rehashed many times here, mostly
because folks treat the R7 like a quarter wave vertical -- which it isn't
and the R7 has that complex matching black box design which I wouldn't mess
with by adding radials. Unless I had the proper test equipment and expertise
to determine what effect added radials have on the impedances and matching.
Cushcraft undoubtedly did this.

More at URL:
http://lists.contesting.com/archives/html/Towertalk/2003-08/msg00059.html

AND http://dayton.akorn.net/pipermail/towertalk/2001-March/037180.html

Regarding decoupling the feed line -- Cushcraft recommends an RF choke 8
inches in diameter and ten turns on the coax.

Me -- I trusted Cushcraft and followed their instructions. Been working
great for 6 years now.
I won't run out the brag tape on countries worked with it -- means nothing.

Source record: 94946

With a typical ground plane antenna, the feedline can radiate
significantly, distorting the pattern. This effect could easily be
different for the different antennas. Modeling indicates that two baluns
are often needed to suppress the current on the outside of the feedline.
A model which includes the feedline might give some insights as to why
the antennas behave so differently.

People like to simplify things, to make them easier to understand. They read that radials are important, but don't understand why, and apply that "sound bite" to all vertical antennas. (Or even to all antennas.) This sort of binary thinking -- or rather, non-thinking, is commonly applied to politics and a vast number of other fields besides antenna theory.

When you put power into an antenna, a current flows out of one conductor of the feedline to supply that power. An equal and opposite current flows into the other conductor. In the case of a grounded vertical, this means that whatever current flows into the base of the antenna also flows through the ground -- where the feedline shield is connected. Due to the resistance of the ground, this results in I^2 * R power loss. If the antenna's radiation resistance is comparable to or lower than the ground resistance, the fraction of applied power that's lost is significant, so it's common to lower the ground resistance by using radials. Radials become increasingly important as the vertical gets shorter, because a short vertical has a lower radiation resistance. However, the feedpoint radiation resistance of a half wave vertical is very high -- typically higher than the ground resistance. For a given power input, a relatively small current flows into the base of the antenna, so very little current flows in the ground. Consequently, the ground loss is low, and there's no need to decrease its resistance with radials.

I recently acquired an ldg lz 100 and hooked it up as soon as I got it. The dipole I have now will tune with a manual tuner to below 1.5:1 on 40m-10m. The autotuner won't tune to below 1.5:1 in any band. Am I doing something wrong or did I just not get a decent tuner. I oftentimes won't even get an SWR green light to show it has tuned and when I do, the SWR is high. Should I put a balun on or what? The dipole is 66 feet long in my attic... but as I stated, it tunes awesome with the manual tuner. If you want to email me, please email to ki4bbl@arrl.net The email here is incorrect.

> buying, and I'm not sure if that matters.

Which one would you be buying and how is it different? Most of the
data in the W4RNL site is for a 90' T2FD. When you look at the gain
curves, remember that they're in dBi. A simple halfwave dipole has
about 2.2 dBi gain.

The T2FD isn't a new invention - it was in QST about 1948 as a
receiving antenna, and that wasn't the first article on it by any
means. Government/military folks wanted a receiving antenna that was
essentially omnidirectional and would give a decent match to balanced
line over the HF frequency range - possibly feeding several receivers
via an active receive coupler. Low efficiency below 8 or 10 MHz was no
big deal because the receivers had lots of gain, and atmospheric noise
dominates in that part of the spectrum even with a poor antenna.

Transmitting is another issue.

If you want to spend the money for a T2FD, enjoy. But in the same space (T2FDs are not small!) and for the same or less money you could have a much more efficient transmitting antenna.

Roy, I've always maintained that when I don't know that the ground resistance is zero, I want as little current flowing in it as possible. My inverted "L" is a voltage fed half wave on 160 meters, about 70 feet up and 170 feet out courtesy of a couple of strategically placed Oaks . I have measured that feed impedance as being in excess of 2600 ohms and feed it with a remotely tuned "L" network. I used it for several years just fed against 60 feet of 6 inch well casing, and then, bowing to conventional wisdom as advertised on 1850 KHz, added an elevated counterpoise beneath the whole thing. (About 12 feet in the air) I didn't notice any change in signal reports, but that impedance sure changed a lot. Did I change something besides the ground resistance?

Regards

W4ZCB

Yeah, and page one:
"System Grounding"

One radial good.
More radial bad.
Yeah, sure.

In fact a word search against the quote above returns 0 hits. So much
for explicit statements and what "should" be read. I note the links
below have the same breathless nature, which is to say a lot of air.

>Do you know what is in the black box matching unit ??

Yes I do.

> If not see URL:
>http://www.iol.ie/~bravo/r7_vertical.htm

Another "should" be read? I think not. It's been posted here many
times over the years and doesn't even broach the topic (the word
"radial" appears nowhere).

>A local Ham added radials -- couldn't tune the antenna -- so he added a
>tuner. When he ran a kilowatt into this mishmash -- the black box blew up.

>So he repaired it as in URL:
>http://www.iol.ie/~bravo/r7_vertical.htm

And this proves what (besides a penchant for repetition)? Another anonymous lid? Thanks, but no thanks, we have our quota here; too often appearing in the guise of learned lecturer complete with Cliff notes. This doubly quoted link does not describe the event you allude to, and in fact offers trap construction is more problematic than the invention of radials-as-evil.

>He no longer has the added radials and tuner and runs a KW all the time with
>no ill effects -- let the experimenter beware.

Yeah, now there's a line - no experimentation in Amateur radio. We have enough Credit Card operators.

>I know this is a controversial subject -- rehashed many times here

Ah, the voice of experience. I've been here 10 years and haven't seen this soap opera yet.

> mostly because folks treat the R7 like a quarter wave vertical -- which it isn't

Repetition again, quite boring now.

>and the R7 has that complex matching black box design which I wouldn't mess

"There is no grounded part in an R7 type antenna"

Which, of course, negates page one of the quoted manual above....

>AND http://dayton.akorn.net/pipermail/towertalk/2001-March/037180.html

"The R7, like others in the R3-R8 series from
Cushcraft, use some number of 39" 'radials'...
They are not radials"

Quality stuff there.

Again, nothing here evidences the "should" of the "should" be read. The two quotes above offer repetition and no actual technical discussion. But then, this group is the place for that, and rightly so in the face of such tepid offerings.

You should vet your offerings before submitting them as evidence.

>Regarding decoupling the feed line -- Cushcraft recommends an RF choke 8
>inches in diameter and ten turns on the coax.

Excellent advice for the 1960s. However, in the 21st century most correspondents here would appreciate how mediocre-to-poor that would be with a conventional choke looking into a half wave load.

You seem to be at odds with experimentation with this last piece of advice. The link to the match box above suggests a far different means of choking. As this choking method does not appear in the Cushcraft liturgy, are we to assume the antenna will burst into demonic flames if this un-ordained device is used?

>Me -- I trusted Cushcraft and followed their instructions. Been working
>great for 6 years now.
>I won't run out the brag tape on countries worked with it -- means nothing.

That has been demonstratively true here for years.

Now, demonstrate the difficulties that will be imposed (if one follows Thierry's advice) by constructing a model readable by EZNEC that may be offered here for peer review. Testimonials do not pass as evidence in this forum as so many of them for the eh/cfa/fractal clog the system currently.

Hi Danny,

I made the same comparison at 40M. The difference between 120
(quarterwave) radials and 1 amounts to 0.1dB Clip that one down by a
tenth and the difference climbs to an astronomical 0.3dB.

In the inverted L or any antenna with a horizontal wire, there's coupling between the wire and ground. The field from the horizontal wire induces current in the ground under it. If the wire is low, the loss produced by this current can be substantial. By putting an elevated wire under the horizontal wire, you've changed this coupling to the ground, plus you've introduced a new conductor into the antenna. Mutual coupling between this conductor and the other wires will change the impedance.

Modeling will give a lot of insight into what all is going on.

A single ground rod, unless in sea water, has a resistance to mother earth between 50 and 200 ohms. Let's take it to be 100 ohms.

Efficiency of a 1/4-wave vertical, feedpoint resistance = 37 ohms, is 27 percent.

Efficiency of a 5/8-wave vertical, feedpoint resistance = 50 ohms, is 33 percent.

Efficiency of a 1/2-wave vertical, feedpoint resistance = 2500 ohms, is 96 percent.

The difference in radiation pattern in a typical back yard, in the vertical plane, is neither here nor there.

The 1/2-wave antenna also needs the most simple L and C matching network.

But I'd never recommend a ground rod anyway. Not worth the time, trouble and expense unless extremely short of real estate at ground level.

Roy, the problem of choice lies in over-complication by too 'clever', 'knowledgeable' old-wives and gurus rather than under-complication.

Thanks, don't know why I hadn't considered "the rest of the half wave". Not many options other than what I have up, so will pass on the modeling. It's REALLY a very decent performer on 160, 80 and 40, and unobtrusive in the summer.

Thanks Tam, This is exactly what I was looking for. A dummy load is 0% efficient. A B&W dipole is less than 20% on 80m and 160m. It costs a lot of money. There are less expensive ways to achieve 20% efficiency on 160m and 80m. 0% does not radiate (dummy load), a good bad antenna in my opinion is one that radiates, but not too much. And it can't cost too much.

Rrad about a complex remote control unit using VLSI circuits and made
some considerations.
Using a 9V transformer it is possible to switch relays to 4 positions
using the following signals on the antenna cable - with RF chokes and
suitable capacitors to pass the RF, and two dpdt relays at remote end:
1) no voltages
2)+12V with a diode in series with the switch and transformer
3) -12V with another diode in series with switch and transformer
4) 9VAC to activate both relays simultaneosly

very simple, but no VLSI - if that was the point, and no intruder
transmitter on 433.92MHz for the remote control if it was another
point, sorry - I am perhaps to old for those modern type of remote
control......

========================

There's no need to mess about with the antenna. Just connect a crude
attenuator at the transmitter end of the transmission line. This much
reduces the cost of the antenna. It's then just a length of wire.

You should be able to tune the antenna on 40 meters, as it is resonant around 7.1 mHz to start with. 20 meters - maybe. 15 meters should tune okay.

Your manual tuner tunes okay because it will tune a much higher range of mismatches, assuming it is a "T" type tuner.

The autotuner I have seen that has the widest range for tuning mismatches is of all things, an MFJ.

This doesn't mean your tuner is bad, From what I have seen of the LDG's - they are nice well constructed units. I'd keep it and modify the antenna.

That, and a generation of congress (including Gore) who voted in such
a way that we now have a vast pool of untapped bandwidth ... 1 mile
from any consumer's house. They encouraged phase one of a
multi-tiered distribution system that is now in the weeds.

The dot.com explosion invested 10s of billions of bucks in fiber
installation promising video on demand and the next generation of web
connectivity.

The current administration (sic) and their FCC has dropped the ball
and mandated that each market area needs to hammer out their own
connection franchise contracts. 100000 opto-balkan states with the
same scale of efficiency. Need anyone wonder why the utilities make
money moving network data over power lines? This is third world
economics.

Be careful about making generalizations about this. The position of the peak current depends on frequency and the ground characteristics. I believe it's also a function of the height of the vertical. In some cases there's no real peak at all, but an exponential-looking decay of current from the base of the vertical outward. This, incidentally, was experimentally measured and documented by Brown, Lewis, and Epstein in 1937.

From: Dave VanHorn <dvanhorn@cedar.net>
Message-ID: <APudnb7MgIWDFzDdRVn-uw@comcast.com>
Source record: 94971

What sort of antenna offers narrow beamwidth, combined with smooth
sidelobes?
I'm not too concerned with F/B ratio, or the magnitude of the sidelobes,
(smaller is better obviously) but I'm more concerned that they not be a mess
of deep spiky notches.

This is a somewhat special application above the 440 band, but I could scale
a 440/900/1296 design appropriately. Gain, per se, isn't really an issue,
and negative gain may in fact be acceptable.

Richard,

But they promised things that no one needed or wanted! They promised connectivity almost as ridicuous as AT&T promises in the early 70's - like the video phone, which made about as much sense as computers in the shower. It never went anywhere and to this day, even when it is free via the internet, it has no market. Satellite radio in cars, while it sounds like a good idea, struggles financially after third and fourth generation bankruptcies of the successors. No one wants to pay for it, and they have to give it away in new cars. There's a new "Palm Pilot" born every day. The next big false start I'm watching closely is "software radios". DOD is being sold a big bill of goods on these, and FCC is sitting on their hands unsure if it will revolutionize, or destroy the bandwidth. I'm a big defender of property and intellectual rights, and despise frivlous lawsuits, but I hope Motorola is held accountable for the miserable product they sold NYC public safety agencies. They aren't just short a few hundred towers there, they have a product as miserable as Nextel digital - it drops off at almost any corner with no fail-soft analog reliability.

>
========================

Danny, I quite agree.

The current-carrying cross-sectional area of the Earth is enormous at distances from the antenna base of 1/4-wavelength and greater. Regardless even of very poor soil resistivity, loss in the soil is sensibly zero.

Furthermore, propagation velocity in the soil is MUCH less than the free space velocity and I am of the opinion that computer models give a very distorted picture of what actually happens.

At distances of the order of 1/8 free-space wavelength practically all of the current flows in the soil. Shallow-buried radials might just as well not be there. The copper is better used to increase the number of short radials.

But an increase in the number of short radials is a waste of copper anyway when the number of radials is already very large.

What B,L&E were doing with 120 radials at MF in 1937 is hardly relevant. I understand they forgot to determine ground conductivity - an indication they didn't fully appreciate what they were about. As they were the first in the field to make such measurements this omission is understandable. But at HF, soil characteristics are considerably different - factors which computer model users do not feed into their models.

Computerised antenna model users are inclined to suffer from delusions of accuracy - drowning, unaware, in a sea of uncertainties.

But there's no real harm done! ;o)

It's quite possible. The 1/2 was the only one I actually added a
decoupling section to. It was a 1/4 wave length of coax below the
feed, and a grounded set of 1/4 wave radials at the base of that
section. About the same scheme as cushcraft uses on their ringo ranger
2 verticals. It did improve the antenna. I never added extra
decoupling to the 1/4 or 5/8 antennas. But I did try both 1/4 and 3/4
wave radials on the 5/8 antenna. Ended up prefering the 3/4
radials..The 1/2 wave was a very good antenna, but in my case, not
once did it ever beat the 5/8. Actually, thinking about it, and even
included many CB antenna setups going back years and years, I've never
seen a 5/8 GP that didn't handily beat a 1/4 GP by 2 S units to a
local ground wave station. Even using the 1/4 wave radials, which I'm
not crazy about for a 5/8 antenna. These were all using various
length feedlines I'm sure. MK

>sidelobes?

I don't know what you mean by 'smooth sidelobes'.

Sidelobes are artifacts of truncation and/or lack of continuity, in the spatial frequency spectrum of the aperture.

There are lots of ways, in hardware, to mitigate sidelobes. In an array this is done, conventionally, by amplitude weighting of elements. There are non-conventional ways of course, that are beyond the scope of this NG.

As elelemnts, there are moderate gain dipoles that have no sidelobes. A conventional solution, for example, is a Landstorfer element, which is a curved wire antenna that looks like a Gaussian in outline.

Perhaps a bit more specificity would help.

What is the best way to use one feed line for more than one dipole?
Or, is it better to use a coax switch in the shack?

Thanks, Ron

2480. Re: Two dipoles on one coax

> Or, is it better to use a coax switch in the shack?

Ron, your subject line "Two dipoles on one coax" implies the typical antenna selector switch that leaves no question (of course you can do that). But the message body asks about one feedline for more than one dipole as opposed to the antenna selector. The two choices are so unequal that a comparison is not possible.

Someone may explain here that they have connected more than one antenna with a single feedline, but it flies in the face of proper operating procedure. Most operators however do use antenna selector switches to provide more than one antenna choice to a given receiver or transmitter. The individual antennas always have their own individual feedline in those cases.

Best regards,

Jack Painter

> I don't know what you mean by 'smooth sidelobes'.

I would rather have a higher sidelobe amplitude, if I can also not have deep notches in it, than lower sidelobes with deep notches, unless of course the sidelobes can be made to be insignificant.
And at this point, I'm not sure how low they would have to be, to be insignificant.

A small dish is possible, but given the wavelength, "small" is not really all that small.
I don't get a choice on wavelength.
In order of importance, tight beamwidth, low sidelobes, "smooth" sidelobes, and gain.

It probably would, but I'm just at the back of napkin stage on this project.
I won't know what I need really, till I do some testing.

Ron,

Connecting two *dipoles* to the same feedline works just fine. Just tie them directly to the same balun. There will be two kinds of interaction: first, the two are electrically in parallel, and second, the wires themselves could have mutual coupling. The first seems to not really be a problem, and the second is minimized if there is separation between the two dipoles. For best results, put them at right angles to each other; if that is not possible, have at least 15 - 30 degrees separation, either vertical or horizontal. For instance, you could have a dipole supported at the ends, with an inverted V hanging below it.

The most interesting case is for antennas at 75 and 80 meters. You get <2:1 SWR from 3.5 to 4 MHz in a virtually non directional antenna (if the two dipoles are at 90 degrees).

I presently have a 40 m inverted V hanging below an 17 m dipole. (The trees are too close to do it the other way). The 40 meter is also out of plane to miss the trees. Works great.

Since you have to trim the lengths slightly (lowest frequency first), it is simplest to run EZNEC or some other simulation first.

An Extended Double Zepp has a relatively narrow beamwidth
(~35 deg) and four side lobes about -13 dB down. I vaguely
remember a magazine article that told how to virtually
eliminate the EDZ side lobes.

Ron,
It's mainly a matter of convenience, or maybe you only
have enough feed line for one feed line.
Depending on 'how' you use the connected-together antennas,
only for use on the intended bands they are cut for, or as
multiband antennas, it might be simpler to use seperate feed
lines for each.
As for the 'best' way of connecting two or more antennas
for use on a single feed line, attach them to whatever you're
using for a center insulator, the second antenna just like the
first one. There are a number of 'mechanical' ways of doing
that and the 'best' is which ever is easiest for you (or how
ever you know how to do it). As you'd expect, the connections
should be strong enough, light weight enough, and sort of
'pretty' enough to satisfy the antenna's requirements and any
'significant other' that's around (wife, neighbors, landlord,
etc.).
Using seperate feed lines and an antenna switch makes the
process of tuning the antennas a bit 'easier', probably won't
take as long. Which ~may~ be the only difference depending on
how/where you erect the antennas.
Of course, using antennas that are high, widely seperated,
and
fed seperately is always nice! If you have the room, the
required
feed lines, a switch, the time to do it, and so on (I wish!)...
'Doc

Greg,
Most 'auto-tuners' have limited tuning 'range' when
compared to 'manual' tuners, that's because of expense,
size limitations, and so on. Since I know nothing about
your 'LDG' tuner, that's what I'd have to guess is happening.
Doesn't mean that there's necessarily anything wrong with
it, just that it can't 'do' what you're asking of it...

Richard,

I don't know the answer to the main issue of this thread. I just
don't know enough about antennas to speak as an expert. However, as a
point of fact, the R7 manual does state on page 1 under the section
titled "Location":

'Although the R7 will operate in almost any location, it will perform best if it is mounted vertically and located in the clear away from surrounding objects such as buildings, trees, powerlines, towers, guy wires, antennas and metallic objects. The R7 should not be attached to a ground radial system. Failure to heed these points will possibly degrade performance, detune the antenna and increase VSWR".

When I clicked on the above link, a PDF file was opened. It appears that the manual was scanned and stored in PDF. In this case, no text search would be successful.

FWIW, when I added radials to my R7 I was unable to tune it properly on all the bands. Once the radials were removed I was able to tune it up without problems.

Thanks,

Rick, K6RJ

>Like nylon, possibly using a dab of epoxy to hold them in place?

In principle this ought to be OK. The presence of the standoff will
have some effect on the antenna's electrical behavior (increased
capacitance between element and the reflector) but I suspect that this
would probably be negligible in most cases. Depending on the
frequency in question, you might want to select a standoff material
which is known not to absorb RF at those frequencies. If you're
really feeling energetic, don't use nylon and epoxy - fabricate
standoffs out of Teflon, with a hole-and-slit arrangement to admit and
hold the antenna element, and a tapped hole in the base to allow it to
be secured to the reflector plate with a nonmetallic screw.

Oh well.

2499. G5RV or 135 foot doublet or Carolina Windom?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-21 19:41:53 UTC
From: Jim Leder <k8cxm@fuse.net>
Message-ID: <3Ysrc.39$ax2.9@fe37.usenetserver.com>
Source record: 95002

This topic has been kicked around so much, I feel like it fits into the upcoming spring/summer TV reruns. I currently have a G5RV in an inverted Vee configuration, with the apex at about 35 feet. It works OK on 75/80, pretty well on 40, OK on 20 and OK on 17. It is a miserable failure everywhere else. I'm limited in space and height, but after surveying my trees and lot, I could put up a 135 foot center fed doublet with the apex at about 40 feet and the ends sloping down to about 15 feet (another inverted Vee, best I can do with my trees). I would feed it with 450 ohm ladder line to the shack, mate it with a 4:1 current balun and then connect with a short piece of coax to my TS450's ATU. Seems like it should work, but I guess I need to ask some questions:
1) My G5RV is old, and has been patched. I expect it to not survive another winter or the vinyl eating squirrels. Does the doublet offer me any improvements? The ladder line would be away from the hungry rodents, free swinging and not near their trees.
2) Or, should I just rebuild the G5RV and scrape the doublet idea?
3) Is the 4:1 balun a good idea? Seems the only good way to be able to use the Kenwood's ATU. The G5RV and Kenwood work well together on all bands, even though it doesn't radiate out of my backyard on some of them.
4) Should I be concerned with RF in the shack with the doublet scenario?
5) Is there a better doublet length than 135 feet? That seems to be the most common length I see.
6) My intention is to replace the RV with something better, that offers improved performance on 75/80,40,30,20 and 17. Is it LIKELY this setup will work, or am I too optimistic? I have an Alpha Delta DXEE which would be moved to where the G5RV is now, offering me 20,15 and 10 (it's bad on 40).
7) I've spent a bit of time looking over my situation, and this is maybe the best wire antenna installation I can come up with. I've also considered making my own 'Carolina Windom', but from what I've read it doesn't offer me much improvement. Does it? Might the 'Carolina Windom' approach be a better idea?

My goal is to keep the replacement costs below $35, which I know I can do with the doublet or the homebrew 'Carolina Windom'. I'm in no hurry, got all summer to do this and I am retired. I just want to do what will give me the best results. I'm looking for opinions, suggestions and practical experience with using one of these doublet/balun antennas or 'Carolina Windoms' and the kind of ATU found in most modern transceivers. I don't want the hassle or expense of an external antenna tuner.

Thanks...and 73's from Cicada humming SW Ohio

What do people think about EH aerials? Opinions are certainly divided here in Poland.

My biggest concern is that it is very hard to get any real construction details of these aerials, which kind of leads me to beleive tha tthey are basicially a big coil and not much else whihc would radiate in any shpae or form.

Would be delighted to hear others opinions, expereriences.

Richard

>point of fact, the R7 manual does state on page 1 under the section
>titled "Location":

Hi Rick,

Thank you for the follow-up. You are correct, and yes the pdf is a
poor, unsearchable copy as evidenced by your observations offered.

As far as this thread goes, I've seen testimony that it works/doesn't
work with radials - both ways. Such is the value of testimonials
where you can find any answer to suit any occasion.

I've seen testimonial "proof" that an eh works better than a standard
quarterwave, wherein the data clearly proved it didn't. The
testimonials dismissed the data (their own) as irrelevant.
Testimonial is fine and is occasionally called for. Testimonial as
proof is worthless.

I've offered data to this point of a "prohibition" on using radials.
The difference between 120 quarterwave or halfwave radials compared to
one short "counterpoise" barely tipped the meter at 1dB on the
performance side of the ledger. As for matching, I averred that
tuning may be impacted (I cannot imagine how it could be otherwise).
THAT is within the provence of Amateur radio service as a minimum
technical skill. THIS is a technical forum where design and data is
offered for examination. The remaining correspondence is confined to
the slow lane or the shoulder when a rhetorical axle is broken.

Frankly, this "prohibition" of no radials is more a design mandate,
not a papal bull. The site offered where we can find the actual
components of the "black box" displayed and laid out schematic style
offers an equal opportunity to redesign to allow radials. This
apparently is not within the skill-set of many, or arguably even
desired; however, it is not impossible (nor particularly difficult).

To this last point. I would offer that most of the interesting
correspondence (that isn't simply entertainment quality) is composed
of rather academic interests. Some of it is impractical in the
extreme and as absurd as fractals. More of it barely offers a
difference that would twitch an S Meter, or a Power meter. This does
not mean it lacks merit in its discussion because, let's face it, a
forum is built and survives on the vigor of debate. Clearly no one is
going to (legitimately) re-invent the dipole, so topics become rather

obtuse.

The general feeling here is that they are not what their advertised to be.
In fact most real tests show that most of the radiation from one is from the
feedline, not the antenna. Bottom line is they don't work and a light bulb
on the end of the coax would work better.

Thks for replies. I am going to keep it. I think it will come in handy for FD when I run a random wire up a tree. I will certainly look into some of the specs for this tuner and adjust the antenna accordingly. Shows my ignorance that you can just throw up an antenna and tune it with an autotuner. Thanks again. Always a big help!!

>eliminate the EDZ side lobes.

It was in the vol. 4 Compendium, and it is also in my latest ARRL antenna book. The technique involves placing about 2500 ohms capacitive reactance on each leg of EDZ at a strategic location. You can reduce the side lobes, and provide a better match to 50 ohm coax.
I have been playing around with a 3 element 2 meter EDZ beam that is currently 17 dbi gain @ 3 deg. elevation with 12 dbi F/B. I used side lobe reduction on all 3 elements. Be interesting to see if the actual antenna matches the model.

Gregg,

Measure the SWR without a tuner on the various bands. you should be able to
tell whether the autotuner will tune that.

That's what I wanted to hear, that it can be done without using
anything special. It sure would beat switching them at the xmitter. I
have always used separate feed lines and recently I read where someone
had 4 dipoles on the same feed line.

>
>The most interesting case is for antennas at 75 and 80 meters. You get <2:1

2514. Wizard Radio in Seven Corners, VA, to receive WHFS in Annapolis

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-22 00:30:48 UTC
From: dgoncz@aol.com.bat.exe
Message-ID: <20040521203048.07231.00001969@mb-m02.aol.com>
Source record: 95018

Dear Amateurs,

What might I do to improve reception of WHFS using my Wizard Radio ISA card?

I am troubled by mono reception due to insufficient signal strength, movement and position of people in the room, and interference pickup.

If I could just get some shielded twinax... I need less than 20 feet:

Because the antenna, Radio Shack's best passive antenna, is hung from the center of the 15 by 15 foot living room, and is connected by a hook directly above the computer with 300 ohm line. But it isn't an ordinary line.

I figured the end of the 300 ohm line needed to be just like the end of the dipole that came with the Wizard, so I cut down the center for about a foot, shaved off the center and spaced the two lines gradually with dental floss to make an "adapter", ending with them close enough together to be soldered to the tabs on the 1/8 inch three conductor phone plug that goes into the Wizard.

What I want to try now is get some 72 or 78 ohm twinax, use the braid gounded to the barrel of the plug to prevent interference, and terminate the braid at the tip of the antenna with an insulated mount made from Lexan with a square hole fitting the end plug, and a hole to pass the two inner wires. From there, I'll run the inner wires, braid free, to posts extending the existing antenna terminals so that they run in a plane parallel to the main beam.

Is there a spacing pattern I can use for this 28 inch run? Or should I tension the wires to make a linear spacing pattern from the posts, which are 1 7/8 inches apart, to their entry into the braid at the end of the antenna?

I have already tried a balun but have not tried a 300 to 75 ohm balun at the antenna, shielded line to the computer, another 75 to 300 ohm balun there, a length of 300 ohm line, and a cut down the middle of the 300 ohm line to space the wires closer and closer together until the entry point. Seem like too many losses.

Thus the twinax and posts. It has the correct impedance at the entry to the Wizard, maintains it, shielded, to the antenna, and then the shield terminates and the wires form an air space line adapting to the antenna's presented terminals. Presumably two air spaced lines there would have 300 ohm impedance.

The antenna has a smaller front passive element, a second passive element at 23 1/2 inches along the beam from the first element, an active element 3 1/4 inches from that, crossed lines to another active element 1 foot from the first, another pair of crossed lines to an active element at 13 inches, and a passive element at 16 inches from the last active element.

The lengths are passive, shorted, 49 inches, another just like it, active, open, 43 inches, and then 56 inches, then 58 inches, then the final passive, shorted element 66 inches. The shorted elements are shorted together and to the beam. All elements fold with care, but I broke one passive element latch figuring that out. You have to pull the latch to fold the element. They're all nearly parallel. They can all be refolded and redeployed with care. I intend to keep this antenna for a long time. I just love my WHFS.

This is a distance of about 55 miles over roads.

The antenna is rated to 110 miles.

The Wizard obviously has a weak input section, but it has tuning in 0.05 MHz steps.

I can receive WHFS on 99.1 MHz, and on 99.05 and 99.15, but at 99.0 there's another station from 98.7, and at 99.2 there's a station from 99.5.

[98.70] [99.00](99.05)(99.10)(99.15)[99.20] [99.50] tuned
[98.70] [98.70](99.10)(99.10)(99.10)[99.50] [99.50] received

like that, see. During the day. At night it's worse.

Yours,

Doug Goncz (ftp://users.aol.com/DGoncz/)

Ok, I spoke to the designer this evening, and I'll pass on what I learned. He was speaking fast, as he normally does, so I'm sure I missed a lot. Roy can confirm that, and Roy can confirm that he handed over another copy of his software to him just last week.

Per the designer

The R7 was built because he needed a multiband antenna in the fall of 90. The R5 was used as the base idea for the design. He worked on it over late fall and winter 90/91. The antenna project was up and down 2 to 3 times a day at times.

The owner of Cushcraft heard of the backyard project in spring 1991, and "asked" that it be brought to work. Tomorrow at the latest.

The antenna is not a half wave antenna, it is about a 3/8 wave antenna. The impedance is approximately 250 ohms, and a roughly 4.5 to 1 transform is done. There is a series cap of 41 pF for 40m.

There are 7 radials of 49 inches, because Cushcraft had tons of 49 inch 5/8 whips for 2m. The R5 had 4, this needed more.

There is a false resonance on 75m or 80m, and if you put power into it at that freq, you will burn up the matching system.

And, to end this argument, do not ever add radials to the system, and do not remove any of the ones it comes with. It's a touchy match.

If you want to run coax, how about a fan dipole? That seems to me to be
the best of all worlds. Youjust have to spend some (more) time trimming
since the wires interact with each other.

OM,

Since a dipole will also work on the third harmonic of its design frequency, it's very common to use a 40 M dipole on 15. You usually don't need a second dipole to work 15 if you already have one for 40.

As other have pointed out, however, it's perfectly fine to put dipoles for other bands on the same feedline: 20, 17, or whatever. The antenna that's not in resonance presents a high impedance to the feedline, and the resonant dipole takes the power.

HTH.

The 40 is not at right angles. Only shifted horizontally enough to clear the
tree trunks and find suitable anchors for the ends. Vertically, there might
be 30 degrees separation, since the ends of the 17 go up, and the ends of
the 40 come down

> >Since you have to trim the lengths slightly (lowest frequency first), it
is

That is because the 40 has more effect on the 17 than the 17 does on the 40.
I am using a 1:1 balun. Not sure if that affects anything or not.

I see Much better. I need to read and understand.
From what I see at the moment, the corner reflector gives me the smooth and minimal sidelobes I wanted, but not as much directivity as I'd like.
Still, it's a start.

> > to my TS450's ATU. Seems like it should work, but I guess I need to ask some
> > questions:

I don't really recommend that myself. It might work, actually, it
probably would work, but it's hard on that tuner which is not really
made for that type of job.
I would always use a heavier duty outboard tuner if I wanted to run
ladder line.
But thats just me...The tuner in that 450 if fried, costs some hefty
cash flow to fix. It's not made for the real wide impedance variations
you will see with the ladder line fed dipole. It's more of a line
flattener. IE: handy to let you work the whole 80m band, once you are
externally in the ballpark. A 3 or 5 to 1 mismatch is no problem. A 20
or 40 to 1 is gonna hurt it I bet. Will run hot. Might even refuse
some loads, tune, tune, tune, no go, and the tuner will shut off in
disgust. I've seen it happen...

> > 2) Or, should I just rebuild the G5RV and scrape the doublet idea?

Well, maybe not. But I'd find an outboard tuner for the doublet.

> > 3) Is the 4:1 balun a good idea?

Many recommend a 1:1, but the garden variety 4:1 in most tuners that
accept ladder line will work for most matches. I just use the 4:1 in
my tuner if I run ladder line. Not the greatest from a purist point of
view, but I'm not *that* picky....They seem to work for me most all
the time. I always use the min inductance tuning. Very important.

Seems the only good way to be able to use
> > the Kenwood's ATU. The G5RV and Kenwood work well together on all bands,
> > even though it doesn't radiate out of my backyard on some of them.

It's no secret I'm not a fan of G5RV's...:/

> > 4) Should I be concerned with RF in the shack with the doublet scenario?

Not really.

> > 5) Is there a better doublet length than 135 feet? That seems to be the most
> > common length I see.

The best is what fits your bands the best. The best way to find the
best compromises, are to model them. In general, I see the worst
problems on the highest bands, where the dipole is quite long. Using
130 ft 80 m dipoles with ladder line, I've had cases where 10m acted
like a cloud warmer. But the antenna was fairly low to the ground.
Naturally, a half size dipole is bad news also..Lots of tuner loss in
most cases...T net tuners hate half size dipoles...:(

> > 6) My intention is to replace the RV with something better, that offers
> > improved performance on 75/80,40,30,20 and 17. Is it LIKELY this setup will
> > work, or am I too optimistic?

naw. I think it would work pretty well for 80-17....Just get the best,
and biggest tuner you can afford if you do it. You will have lower
losses in general compared to some of the little tuners. IE: I'm using
a MFJ 989c..Not the best in the west, but quite usable for ladder
line, or coax...It has a roller coil, so the inductance setting is
exact. This reduces loss if you are careful tuning.

I have an Alpha Delta DXEE which would be
> > moved to where the G5RV is now, offering me 20,15 and 10 (it's bad on 40).

It's no secret I not a fan of windoms or any OCF dipole either...:/
Those are prone to rf in the shack problems if you aren't careful.

> the best of all worlds. You just have to spend some (more) time trimming
> since the wires interact with each other.

For under $35, this is by far, the best choice I think. Heck, as far
as I'm concerned, it's the best choice at any price...I run parallel
dipoles on a single coax feed. Very efficient, and no ant band
changing required. Right now, I have 160, 80 and 40. Being I tend to

work less 160 in the summer, I usually convert the 160 dipole to 20m, by adding insulators at the 16 ft points...I have two other 160 antennas anyway...I use three of them in the winter...The parallel dipoles will outperform all the other choices on the bands it's resonant on. And you have a dipole pattern on all those bands. The only drawback is if you want all bands to 17m, you have to have about 4 dipoles. 80, 40, 20, 17. The 40 dipole will work 15 using the 450 tuner. You probably could work 10m, using that tuner with usable performance. I doubt the SWR would be over 5 to 1 with the mix of all the elements. In fact, I think my SWR is pretty low on 10m, even without a tuner. Same for 6m...Parallel dipoles are easiest to tune if you spread them apart quite a bit. Don't stack them on top of each other with spreaders, unless you want a real PIA to tune. Lots of coupling between the elements if you do that. I place them at right angles if possible, IE: 80/40 and then the other bands equally in between those. Always start with the lowest band first, then tune each higher band. If you have coupling problems it will show up on the higher band element that is being effected by a lower band element next to it. You will almost never have a problem on 80m. Only the higher bands. Sometimes just moving a wire a few feet, can drastically reduce some coupling you might see. MK

2538. Dipole/Balun? Commercially Produced Alternative?

Hello all. I'm thinking about a wire antenna ... even thinking about buying a pre-made 40-10m (short) antenna ... I have about 40' to play with on the 11th floor balcony facing due west (USAF member stationed in Ankara, Turkey). I also have a tuner that I've never used. I think I'm primarily interested in primarily 10, 20 and 40 ... and perhaps 12, 15, 17 and 30? I'd love to work Europe and possibly back to the states if possible (barefoot).

I happened across an ad for Van Gorden Engineering baluns & insulators, Hi-Q 1:1 or Hi-Q 4:1 Baluns. I have no clue as to how to choose one beyond knowing they connect coax to a dipole. Is coax length important?

Can anyone explain how I'd choose and install a balun given my desire? 1:1 or 4:1 impedance ratio?

Finally, can anyone suggest an off-the-shelf antenna based on their experiences with it?

Thanks!
Rich

Hi all. I'm sitting here trying to figure out how to get on the air!
I'm in a big apartment building ... I have these hot water pipes which
feed radiators on every floor ... I'm on the 11th floor.

I'm thinking that I can throw 100' wire out the window (to radiate)
and ground to the hot water pipes. Thoughts? Any risk of damage to
the heating system? I don't know how the water's heated...

Thanks,
Rich

How much power are you planning to run? You could make the radiators hot with rf, too. The cold-water pipes would be better, as they usually go directly into the ground, whereas the hot-water system goes into a boiler. There are a lot of joints in both between you and ground, so it may not matter much. The pipes won't be very close to true ground potential but may work as a counterpoise to your wire. Worth a try.

When I lived in Manhattan's East Village in the 1970s, I was on the third floor of a six-floor building with a fire escape. I scraped 80 years of paint and scale off the metal and put on a 'crocodile' clip when I wanted to get on the air. My counterpoise was a piece of insulated wire running along the baseboards. After working W1AW and mentioning the antenna (the QSL card came addressed to "Roasted Pigeons") I even got mentioned in the ARRL Antenna Book! Using about 200 W I was able to work ZL and VK on 40 CW, and I was surrounded by other buildings. so your wire is worth a try.

Rich,
Will the heating pipes work as a 'ground'? Sure, probably, but you might think about it for just a while. Since the heating system runs to all parts of the building, that means 'part' of your antenna system is running to all parts of the building too (all those electronic devices susceptible to RF interference, you know? Unhappy neighbors?). Any chance of having access to the roof? That would open up quite a number of possibly 'better' options.
And just because it's not a bad idea, have you, or can you find an amateur group in Ankara? I'm sure they could offer a lot of helpful advice, not just about antennas!

I'm not sure 40' is long enough to get on 40 meters. I tried a 44'
dipole (3/8 wave on 40 meters), and it would only tune 30m through
10m. I extended it to 51', and now it tunes 40m, too. It's fed with
ladder line to an antenna tuner, an mfj unit.

You might just put up the longest dipole you can, 40' or so, feed it
with ladder line, and then tune it with the tuner you already have. If
it has balanced line connnections, you're all set. If not, a simple
coax choke will transition the balanced line to your tuner.

I believe that using hot water pipes as a "ground" would be a violation of
the National Electrical Code.

There have been many good articles/threads posted here - many with links to
websites on grounding.
Try googling on ham-radio and grounding ...

If he's willing to use three different feedline lengths, it will work
like a charm and his ATU will be happy. A 130 ft. dipole is covered on
my web page. Driving the SWR lower than 3:1 by switching the length of
the feedline is a snap and then the ATU is happy, usually over the entire
band. For my 130 ft. dipole fed with "450" ohm ladder-line, a feedline of:

88 ft. works well with my IC-756PRO ATU on 40m, 15m, & 12m.
95 ft. works well with my IC-756PRO ATU on 30m, 17m, & 10m.
105 ft. works well with my IC-756PRO ATU on 20m & 12m.
(Note that the difference in 88 ft. and 105 ft. is 1/2 WL on 12m.)

So with an ATU, three lengths of ladder-line cover all the HF bands
for a 130 ft. dipole. Two 4PDT relays are all that are needed to
switch in three lengths of ladder-line. For 100 watts, two OMRON
LY4's work well.

I tried that in a dorm at Texas A&M in the 50's. Every AM radio
and most every HI-FI in the dorm quit working when I keyed down.

>Any feed back?

I have used the BWD-90 for 2 months now, and love it.
I live on a city lot, and this antenna fits and performs better than
any other antenna I have tried. I've tried shortened 75m dipoles,
40 meter delta loops, and all kinds of slopers. all narrow banded and
loaded with city noise. The antenna has made the hobby fun for me
again. It is frequency agile, and has a great signal to noise ratio.
At 80 meters the antenna is only down 1 db from a standard dipole.
At 40 meters it even, there is 1db gain at 20 meters, and 3db at 10m.
(B & W,s numbers, not mine).
The botton line is if you live in the sticks with all kinds of space,
and no noise, you don't need a folded terminated dipole.
you can run wire to the cows come home,
but it's sure nice in the city.
Curt

Corner reflectors are good, but keep in mind that it will challenging to maintain similar SWR, not to mention gain, over the multiple bands of interest.

My standard question: what problem are you trying to solve? At this point it seems a bit open ended to help more specifically.

Unlike other fields of engineering, antennas are one of the few where expertise is acheived by doing, rather than a mere degree. For example, Dr. Cebik is a retired philosphy of aesthetics professor. Most of what I have seen from his antenna work is especially useful to amateurs, which is the audience target of this NG.

>>Any feed back?

If you desire a single antenna with excellent SWR match at many bands, then I am of the opinion that there is value here.

Even the most efficient horizontal dipole is almost useless for DX--the assumed need, not NVIS-- unless it is high up. This is because all low dipoles have low gain at low elevations: Their launch angle is quite high.

I would suspect that typical ohmic losses on the BW are 2-5 dB. The mismatch lsses are negligible.

Getting this well over a wave high at the lowest freq of operation will afford at least that, and probably more, in a gain differential at low angles, compared to an efficient, low dipole.

The point: a high BW antenna will work well. Any low dipole will work poorly. The in-between is a valid issue to ponder.

I'm only interested in a small frequency range. I said that I could scale
designs on ham bands to what I want.

> My standard question: what problem are you trying to solve? At this point
it

I want to minimize signals from off-axis, and then achieve minimum beamwidth
(maximum directivity).
Gain and bandwidth are compromise points.

>to the states if possible (barefoot).

Hi Rich,

With your proximity to the Iraqi theater, I would suggest you check closely with Turkish laws, much less reciprocity to engage in RF communications. I cringe to think of the unforseen complications that may fall on your head. You might even check with your local command, being Turkey used to be (?) one of our "listening" stations.

As for the mechanics of an antenna, if 40' is all you have, you have more than some. In that sense, it is simpler and far more compelling if you gave it a try. No, it won't be a straight match and if it were, it would be very strange (with luck having nothing to do with it). As you have a tuner, enjoy it. The antenna won't be so far off to be a poor performer.

If local laws, the building admin, and some friendly neighbors allow, you might try a larger vertical dipole (I guess it all depends how many floors there are above you).

Oh.... Okay, Tom.

Since you were only asking, and didn't know, it doesn't have much to do
with antennas.

Hope this helps! 8^)

Chip, how did we digress to comparing a "high B&W" to a "low dipole"? When the two are each at their optimal height (and why would we ever compare anything else..) then the dipole has it all over a B&W. I use my (amost 1/2 wave height) dipole only for DX, without a tuner on it's two resonant frequencies and with a tuner on two bands well above, with amazing results. 5, 8, 11 and 15 mhz to Alaska, Equador, Venezuela and Canadian Maritimes, if that qualifies as "DX".

2556. Re: Antenna Tuner/Coupler Ground ... Hot Water Pipe?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-22 18:36:57 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <c8o6k9ti1@sparta.btinternet.com>
Source record: 94911

Assuming the hot and cold plumbing is mostly metal pipes.

If possible run more than one ground connecting wire in two or more different directions. Even long, bent wires are far better than none. If possible also include a wire to a cold water pipe. Run wires unobtrusively under carpets, etc. 18 gauge to 14 gauge, bare, enamelled or plastic insulated wires will do fine.

Don't forget all the mains wiring in the building (and equipment connected thereto) is also connected to your radio and form part of its ground system. Every bit of stray inductance and capacitance adds to its lectrical bulk.

Make as much use as possible of the large set of random, cross-connected, terminated radials in the building. In principle, you have at your disposal one of the best ground systems for miles around. Connect directly from the transmitter to it as often as you can.

High voltages between pipes and wiring and nearby equipment are very unlikely to exist because of the large electrical mass of the whole. And it is impossible to put one bare foot out of the window to reach the real ground while turning on the cold tap with your bare hand in the bathroom.

To be absolutely safe start with low power before attempting 100 watts. Don't exceed 100 watts. I say this simply because I've never used more than 100 watts myself when using the plumbing system as a ground. Never had any trouble with RF burns. Not even tingling. You and the transmitter are inside a sort of random Faraday cage.

If an occasonal interference to TV is a problem tackle it from the TV set end.

Problems, if any at all, get better the lower the frequency. There may be only one band affected. So avoid it. I've never heard of a problem on 160m. And problems do occasionally arise whatever the ground system when used with an end-fed wire. Or even with an HF rotateable beam fed over a balanced line.

With a high random 100 foot wire out of the window, plus a tuner, you will do very well. By extending the end downwards to make 140 or 150 feet you will do even better.

The only unavoidable problem lies in the locally-generated noise level at the lower frequencies.

Reg, G4FGQ

2559. G5RVh COAX feeder lengths dilemma ? Help please

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-22 20:24:52 UTC
From: Smog <james@burrill.co.uk>
Message-ID: <c8ocu3eap1@news8.svr.pol.co.uk>
Source record: 94915

Hi.

I am just in the throws of installing a half size G5RV in my back garden. I am going for the "top hat" arrangement (North / South) instead of the inverted V.

It says on the instructions with the kit that the best coaxial feeder length to stick to is either 45 feet or 90 feet. I have 77 feet of Belden coax and didn't really want to cut it ! How critical is the 45 feet coax length ? If I have to cut it I will but as said, didn't really want too :(. Could I just leave the 77 feet and neatly fix it around the edge of the garden, to use up the excess, and not suffer too much loss ??

Any help will be greatly received,

Thanks.

I'm certain this question must have been dealt with before,
but I recently acquired a Cushcraft R5 vertical which looks a bit
weather-beaten.

I was wondering whether, if I aerosol-sprayed the aluminum,
elements, with an appropriate color, it might impair the performance
of what is already a compromise antenna. I know radio waves don't care
about appearance, but I would like to "tart it up" a bit.

Thanks for any information.

Good question.

Personally, I'd rather buff it up with steel wool, a wire wheel, and scotchbright pads. Shouldn't take that long. YOu'd have to clean it up in order to paint it anyway.

Certainly, be careful in your choice of paint.

Blair,

John Tait, EI7BA has a good web page on the Cushcraft R5/R7 antenna
http://www.iol.ie/~bravo/r7_vertical.htm

My preference for aluminum is NOT to paint it. Shiny aluminum can not exist
long in an
oxygen environment without developing a dull gray patina (reaction of AL
with O2).
This patina is conductive.

I do not like to use steel wool (dissimilar metal abrasives) and any small
iron/steel particles
left on the antenna will rust (brown).

I usually use a scotchbrite-type pad ... a very mild lye (sodium hydroxide)
in a well ventilated area AND plenty of water.
http://www.ccohs.ca/oshanswers/chemicals/chem_profiles/sodium_hydroxide/basic_sod.html
CAS Registry Number for sodium hydroxide is 1310-73-2. This number is
assigned by the Chemical Abstracts Service (CAS) in the United States and is
used as a unique identifier number world-wide.

Once the aluminum is shiny, wash the aluminum well to remove remaining NaOH.

Dry and then apply a clear finish to preserve the shiny. The clear finish
can not be used electrical and RF conductivity is desired (inside
compression fittings of sections).

IF you desire to paint any fiberglass on the antenna, there are a number of
products for the auto and marine industry for

that application.

Blair,

Here is another R5/R7 "clean and repair" web site.
http://home.planet.nl/~fhvgeerligs/Ant/R5/onhr5eng.htm

IF you do use steel wool, use a good damp cloth to remove any steel slivers
that
you may get. A very fine emery paper (400 to 600 grit) may be a better
choice for
corrosion areas.

IF you are going to be near a salt-water environment a clear coat should be
used.

Rich wrote:
> Finally, can anyone suggest an off-the-shelf antenna based on their
> experiences with it?

Not off the shelf, but a 40 ft dipole will work well on 40m
if you can get the RF into the dipole. A quick session with
EZNEC says if you create a G5RV-like dipole, 40 ft. long, fed
with 20 ft. of 450 ohm ladder-line, and install a 1000 pf cap
at the ladder-line/coax junction, it will be close to 50 ohms
on 7.2 MHz. Of course, it will have to be "cut and tried".

Other lengths of ladder-line should allow it to work well on
the higher HF bands without a tuner.

2569. Antenna support ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-23 00:37:16 UTC
From: dada <sman1@stny.rr.com>
Message-ID: <40AFF4A8.61F46210@stny.rr.com>
Source record: 94824

Hi.
I have been thinking of making an antenna support (for center of dipole, support of Jpole, etc)

Was thinking of using 3 4x4 pressure treated lumber 12 foot lengths.

Put them in cement 4 inces aprt (cement will be approx 4x4x4 feet.
Put 3 vertical 4x4 into cement about 2 feet.
At top of 4x4, create a pivot point, and add 2 4x4s between the other 3.

Add another at the top between the two, overlapping the 3 and 2 and 2 and 1 4x4 by about 2 feet.
Using 12 foot 4x4 that would give me about 30 feet.
Will this work ? Would it stand without guying ?
I plan to make this a tilt over at the top of the lower 3 4x4s, maybe extending the
next tier of 2 4x4s with somthing on their bottoms to give more leverage for raising.

Am I nuts ? (well.... I already know the anser to that... but will this work ?

Thanks & 73

I know that any power not dissipated by an antenna is reflected back to the transmitter. Then the transmitter "reflects" this reflection back to antenna, ad nauseum until its all gone. I also know that a short or an open is required to reflect power and I'm searching for which it is, an open or a short. I'm inclined to think it's a virtual open but I'm at a loss to understand that and I wonder if someone has a good explanation or analogy and some math wouldn't hurt.

Hi Hank,

What you describe as reflection and re-reflection occurs between the
mismatched antenna and the tuner that has been adjusted to minimize
power returned to the transmitter. The sole function of the tuner is
to keep this power from being dissipated by the transmitter (common
experience of arcing, denoting a voltage reflection, or thermal
runaway, denoting a current reflection). The "virtual" reflection
(offered by the tuner) is generally know as the complex conjugate of
the remote load, seen at the near end of the line through which it is
returning. This means that the line transforms the phase and
amplitude of the reflection, and the tuner's job is to invert that
relationship to counteract it, and return it to the antenna.

There are both wave descriptions of this process, and lumped circuit
equivalents. Both work, and both describe the same process from
different points of view. One does not negate the other's validity
(unless, of course, you attempt to mix the points of view and demand
consistency in terms - a frequent rhetorical trap here).

There will no doubt be a flurry of denials to this simple example with
contortions of logic to match. As for the math, you will find it by
the reams, once you've been overwhelmed with the arcana of hyperbolic
descriptions of a novel physics that have to proceed its proof.

Keep your eye on how your literal points in your question go abandoned
with these arcane theories.

Ed -

Good catch. Getting ahead of my fingers. To avoid seizing when assembling
the
telescoping elements of your Cushcraft antenna, you should coat the
inner element with PENTROX-A by Burndy. This can be found at any
electrical distributor.
Many Home Depot stores also carry the product.
It is conductive and will avoid seizing between these aluminum elements.

IF you find an older ARRL Antenna handbook, they routinely showed the
construction of a 30 to 40 foot center support
for an inverted "V" using 2x4 dimensional lumber, and base and guy wires.

==========

Dear Richard, you are confusing the matter even further, if that were possible.

The only saving grace about your tedius message is that you yourself eventually realise what a load of overcomplicated nonsense it is.

Reflected power is a mere fiction. Power which is not radiated from an antenna never actually arrives there. In fact it never leaves the transmitter.

All the power which leaves the transmiter is radiated except for that which is lost in the line. It has nowhere else to go!

But for the existence of so-called SWR meters, the words 'forward and reflected power' would never enter people's vocabularies. For the few who

become involved with such matters, the misleading fiction also appears in the language of mathematics.

Names have to be invented in order to discuss mathematical equations in plain English. But there's no reason why they should be propagated, just to confuse, into the real World.

The sole purpose of an SWR meter is to indicate whether or not the transmitter is loaded with 50 ohms.

Reg, G4FGQ

I agree with that last statement - and we can take it a step further.

Each description can do things that the other one can't; no argument about that. But in cases where both descriptions should be valid, then they *must* agree.

This is a basic cross-check that should always be applied... but regrettably isn't.

I should have been more precise in my estimating (I know ... doesn't make sense). I actually have 59' to play with. Dohhht!

Cecil, any chance you can take one more look-see for me with EZNEC? How well do you think it will radiate on all the bands?

Bob, you make a good observation regarding proximity to theater and Turkish reaction. When I arrived, I filed with the Turkish Telekomuncations Office (their version of the FCC) and got a Turkish Call sign, TA2ZAD. I figured it was appropriate whether I was going to go on the air or not, especially given that I brought a couple of radios into the country. ;-)

I have a separate post going regarding using my SGC-230 coupler ... I was thinking about loading up the hot water pipes as a counterpoise and dropping a 100' of wire out the window. I saw a few folks' replies so far ... and they got me thinking otherwise now.

Thanks!

2579. Conjugate matching and my funky VSWR meter

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-23 08:54:30 UTC
From: Lord Snooty <bonzo@dog.com>
Message-ID: <aFZrc.6955$be.4189@newsread2.news.pas.earthlink.net>
Source record: 94834

There has been some discussion in the past months about conjugate matching, VSWR, and power transfer from source to load.
I've come across a puzzle while noodling on this.
My main issue here is how the heck my VSWR meter is measuring the way it is.

My elementary hook-up is an RF power amp feeding directly into a VSWR meter, and from there into a load consisting of a carbon resistor and a variable capacitor rigged in series. The meter connects to the load via about a foot of 50 ohm coax. The frequency is between 1 and 10 MHz.
Model the source impedance as Zs = R + jX, and the load impedance as Zl = r + jx (or use phasors if you prefer :).
The following two statements are true:
1) The power dissipated in the load (r) is maximised when x = -X (so-called "conjugate matching"), whatever the value of (r).
2) The classical VSWR is minimised (zero "reflected power") when x = +X, whatever the value of (r).

However, my VSWR meter, whch is a conventional 2-diode bridge and short transmission line, indicates that minimum indicated VSWR corresponds to max power dissipated in (r).!! (i.e. at conjugate match, and NOT when reflected power is zero).

The equation normally used for VSWR is
VSWR = ABS((1 + |p|) / (1 - |p|))
where
p = (Zl - Zs) / (Zl + Zs)
and p is a measure of the amount of power reflected back to the source, called the "voltage reflection coefficient"

I plotted something I call "conjugate VSWR" or VSWR*. which is the same expression as above, but with p defined as
p = (Zl - Zs*) / (Zl + Zs)
where Zs* indicates the complex conjugate of Zs.
and the behaviour of this VSWR* thingie absolutely matches what I see on my meter. Aye, there's the rub.

Some points to note
a) Classical VSWR shows NO minimum for all r, when x has the opposite sign to X
b) VSWR* always has a minimum at the same r-value which causes maximum power to be dissipated in r, whatever the value of x.

Again, I flat don't understand how my VSWR meter can indicate VSWR* when I know it should indicate VSWR.

Here are a couple of links to flesh out the theory.

1. Wade through this at your peril - it's you lot fighting abou this issue and is VERY long
http://www.ibiblio.org/pub/academic/agriculture/agronomy/ham/ANTENNAS/20030831.ant

2. This is much more succint - cut to the chase on p47

Hi all. Thanks for your replies. To give you more info, I'm only capable of up to 100w. I'm thinking about adding a Bencher 1.8-30 MHz Bandpass Filter to my set-up to minimize TV interference (even if I use a dipole, ref. my other post, "Re: Dipole/Balun? Commercially Produced Alternative?" The pipes/radiators throughout the building would be the counterpoise to the hot-wire ... not at all intended as a ground. I'm poised to do this rather quickly, minus the bandpass filter, which I need to order from HRO or AES.

So maybe I will try this out... Any last words about safety? Not blowing up the furnace room and heating oil tank? ;-)

By the way, off topic, but can anyone please get me a good e-mail address for HRO? All the e-mail addresses on their web site are inoperable. Go figure. ;-)

Thanks!
Rich

Fiction may not be the right word, but reflected power is certainly a *useless* thing to calculate.

>Power which is not radiated from an antenna never actually arrives
>there. In fact it never leaves the transmitter.
>
Agreed.

After the first microsecond the transmitter is operating into a steady-state load impedance. The only *useful* question then is: "Given that particular value of load impedance, how much power can my transmitter generate?" But that isn't an antenna/transmission-line problem at all - the answer lies in the transmitter, and *only* the transmitter.

As far as the transmitter is concerned, it doesn't matter how that particular value of load impedance was created. There are several ways to create a specified value of (R +/-jX), and whichever way it's done, the transmitter will deliver exactly the power.

> "conjugate matching"), whatever the value of (r).

wrong. you must transform the R+jX along the transmission line to get back to the load seen by the source. you stipulate a low frequency and short line, so you are close anyway.

> 2) The classical VSWR is minimised (zero "reflected power") when x = +X,
> whatever the value of (r).

doubly wrong. vswr is on a cable and is independent of the source. it knows nothing of R+jX only the characteristic impedance of the cable. all following calculations are wrong for this reason alone.

>
> However, my VSWR meter, whch is a conventional 2-diode bridge and short

Hi Jack,

It seems relevant to me in two big contexts: (1) why do some folks do well (relatively) with the BW antenna; (2) what does it replace?

My response clearly explains (1). In the case of (2), I can think of many circumstances where it is preferable to put one dipole (BW) up high than a slew of dipoles up high. If you have neighbors, you know what I mean:-)

Don't know what DX is to me anymore; I have DXCC #1 Honor Roll and haven't been active on the low bands in several years. To someone else, DX is what you haven't heard or worked yet:-) I say go for it.

Some folks don't live in a perfect world, Jack, and its good to know when a compromise is a true degradation.

A BW antenna, up high, is a good antenna for DX across many bands. It is hardly a dummy load.

Hope this helps on this question.

73,
Chip N1IR

Reg:

Consider a signal generator connected through a circulator to the input of a slotted line. The circulator provides a constant impedance to the signal generator no matter what impedance is connected to the output port of the circulator. Now, if your quote below is true, please explain the standing wave pattern measured via the slotted line probe whenever the slotted line itself is terminated in other than its characteristic impedance.

Also ponder this scenario. A transmitter is adjusted to deliver the maximum output power of which it is capable (limited by its power supply) into a 50 ohm transmission line several wavelengths long, terminated in a 50 ohm antenna. The transmission line is just barely rated to handle the power delivered by the transmitter under these conditions.

Now something fails within the antenna, and its input Z rises to 2000 ohms. If the transmitter has no protective circuits to shut it down, it will continue to generate power, and the transmission line will arc/burn. Of course, so might the tx output circuits, but let's say they are "very robust," and the tx continues to operate.

What is the source of the additional power causing the line failure? The tx already was delivering all the power it could before the failure, so it isn't coming from there.

You aren't being literal-minded enough. When you claim to "see" and
"measure" reflected power, you're applying theories that assume it
exists. You are not proving that it does exist.

What shows on your TDR, as ghosts on your TV, and also on a slotted
line, is the interaction between forward and reflected voltage waves.
Likewise a circulator (or a directional coupler) processes the voltage
and current waves. I've yet to see a fully detailed functional
explanation of any of those devices in terms of power waves alone.

That is because "forward and reflected power waves" is a derivative
concept. It depends on concepts of voltage and current waves for its
existence; but it doesn't add anything useful that we didn't already
know.

Modeling of the G5RV shows that the best length for the Coax section
is 0 feet!
The reason is that the coax section only creates loss, depending on
the SWR at the frequency of operation. Some frequencies have higher
SWR than others.

I provide a sample G%RV antenna file with Coax definition in the demo
version of Nec2go. It is very easy to Sweep the coax length and see
the losses.

i know that, i was just trying to get in all the bogus arguments before
anyone else did. 'power waves' are a concept invented to simplify some
concepts, but instead they just hide the important details. we have been
over and over that on here in the past and always end up in the same place,
i was just hoping to skip right to the end.

maybe if i had learned to use smileys it would have helped.... what is the sarcastic one?? something like ;-^ or something like that??

2591. Re: G5RVh COAX feeder lengths dilemma ? Help please

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-23 13:18:46 UTC
From: 'Doc <w5lz@cwis.net>
Message-ID: <40B0A4B6.B54F8150@cwis.net>
Source record: 94846

Jim,
Sorry, but the length of the coax is important. You
have another option (per the instructions), add another
12 feet to the 77 feet you already have.
The length of coax is specified for a purpose, it makes
up part of a circuit which does impedance transformation, and
if you change the 'value' of a circuit's component, you
're-tune' the circuit. The length is fairly critical. Maybe
not to the 'milimeter' level of accuracy, but certainly to the
'foot' level...
'Doc

PS - Are you sure the instructions said 45 feet or 90 feet?

2592. Re: Reflected power ?

If this old mind recalls correctly a TV station with an undesireable SWR
will not transmit a clear image to its viewers because the delayed
re-reflection arrives at the TV set later and casues a ghost or smear.
Could you please explain the "Reflected power is a mere fiction." and the
smear or ghost?

tnx

2593. Re: Antenna Tuner/Coupler Ground ... Hot Water Pipe?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-23 13:34:01 UTC
From: 'Doc <w5lz@cwis.net>
Message-ID: <40B0A849.BAF5CCC0@cwis.net>
Source record: 94848

Rich,
How ever you think of it, the 'steam' pipes are
going to be part of your antenna 'system', they
will have RF on them. Filters may 'help', but they
won't remove the RF from the pipes, and the possibility
for RFI is still going tobe there.
Especially at 100 watts, I seriously doubt if you
have to worry about 'blowing up' the boiler room. I
would be more worried about irrate neighbors...
'Doc

PS - Give it a try. If there are complaints, stop!

That is probably the case in all antennas. Just one slight problem. HOw does the average ham set up a station for the low bands without any feedline ? With some of the remote heads like the Icom 706 I guess that you could mount the rig at the feed point and remote it. Still not too practical for most .

The G5RV was designed to allow a reasonable match on some bnads if fed with a specific ammount of feedline. YOu pick up losses but the SWR will be low into a 50 ohm system. Did you modle the impedance of the G5RV without any feedline ?

Yeah... that's the kicker. I don't want to guy it.

Guy supportsa get in the way of stuff like moving the lawn, and I'd have
to situate the mast in a different location than I would want.

Thanks for the ideas.

Andrew,

Conjugate matching may be a very interesting subject and is indeed a much discussed topic on these walls.

However, amongst the amateur fraternity, a "conjugate match" should be classified as being off topic. It does not exist. Not even when the tuner has been adjusted exactly for a VSWR equal to 1 to 1.

Why?

Because the internal impedance of the transmitter is not 50 ohms. It is not relevant.

What is the internal impedance of YOUR transmitter? You will not find it mentioned in the manufacturer's operating or maintenance handbooks. In all likelihood you will not know what it is even if you designed and built the transmitter yourself!

Reg, G4FGQ

> and some math wouldn't hurt.

Hank, EM reflections are covered on this web page.

http://www.mellesgriot.com/products/optics/oc_2_1.htm

In particular: "Clearly, if the wavelength of the incident light and the thickness of the film are such that a phase difference exists between reflections of p, then reflected wavefronts interfere destructively, and overall reflected intensity is a minimum. If the two reflections are of equal amplitude, then this amplitude (and hence intensity) minimum will be zero."

"In the absence of absorption or scatter, the principle of conservation of energy indicates all "lost" reflected intensity will appear as enhanced intensity in the transmitted beam. The sum of the reflected and transmitted beam intensities is always equal to the incident intensity. This important fact has been confirmed experimentally."

In order for (rearward-traveling) "reflected intensity" to "appear as (forward-traveling) enhanced intensity in the transmitted beam", the momentum of that (rearward-traveling) intensity must change directions. Thus, it appears that total destructive interference between two rearward-traveling reflected waves in a transmission line will reverse the direction of momentum of the energy in those canceled reflected waves.

We need to change a few of your statements:

Any power not dissipated or radiated by an antenna is reflected back. "Dissipation" means EM energy transformed into heat, according to the IEEE Dictionary.

The transmitter/tuner end will not re-reflect 100% of the reflected energy unless there exists a short, open, pure reactance, or "total destructive interference" as explained in _Optics_, by Hecht.

Besides a short or an open, a purely reactive impedance will cause 100% energy reflection. Apparently, so will "total destructive interference". Quoting from _Microwave_Transmission_, by J. C. Slater:

"The method of eliminating reflections is based on the interference
between waves. ... The fundamental principle behind the elimination
of reflections is then to have each reflected wave canceled by another
wave of equal amplitude and opposite phase."

That's pretty clear. We get one set of rearward-traveling reflections
at the match point. We get another set of rearward-traveling reflections
at the antenna. If these two sets of reflections are equal in magnitude
and opposite in phase at the match point, they cancel each other and the
rearward-traveling momentum energy in those two waves is conserved by
changing direction to become part of a forward-traveling wave.

Clearly there is reflected power. Just don't take the SWR meter too
literally. It does not actually measure power, but the scale has been fudged
so it indicates the correct power if the load is equal to some design value.
I can see a long thread here.

Source record: 94855

Richard Clark wrote:
> As for the math, you will find it by
> the reams, once you've been overwhelmed with the arcana of hyperbolic
> descriptions of a novel physics that have to proceed its proof.

A scattering parameter analysis, described in HP Application Note
95-1 (available on the web) is ideal for analyzing what happens
at a match point in a typical ham radio antenna system.

b1 = s11(a1) + s12(a2)

b2 = s21(a1) + s22(a2)

b1 is the net forward voltage, b2 is the net reflected voltage
a1 is the incident forward voltage, a2 is the incident reflected voltage

Quoting from HP AN 95-1: Another advantage of s-parameters springs
from the simple relationship between the variables a1, a2, b1, and
b2, and various power waves:

|a1|^2 = Power incident on the input of the network.
(forward power incident on the match point)

|a2|^2 = Power reflected from the load.

|b1|^2 = Power reflected from the input port of the network.
(power reflected from the match point back toward the source)

|b2|^2 = Power incident on the load.

The previous four equations show that s-parameters are simply
related to power gain and mismatch loss, quantities which are
often of more interest than the corresponding voltage functions.

|s11|^2 = Power reflected from the network input divided by
power incident on the network input

|s22|^2 = Power reflected from the network output divided by
power incident on the network output

|s21|^2 = Power delivered to a Z0 load divided by power available
from a Z0 source

|s12|^2 = Reverse transducer power gain with Z0 load and source

End quote.

b2 is the voltage reflected back toward the source and

b2 = s21(a1) + s22(a2)

It should be obvious that b2 cannot be zero unless there exists
total destructive interference between s21(a1) and s22(a2), i.e.
s21(a1) is equal in magnitude and opposite in phase to s22(a2).

> transmitter.

Therefore, radar cannot work since it relies upon reflected
joules/second. Mirrors also cannot work since there is an ExB
amount of power in those reflections.

Reg, for a 291.5 ohm antenna to accept 100 watts requires the forward
power to the antenna to be 200 watts. 100 watts is accepted by the
antenna and 100 watts is rejected by the antenna. 200 watts to the
antenna is routinely accomplished by a 100 watt ham transmitter and
a Z0-match provided by a tuner.

This is exactly like a partially silvered mirror that reflects half
the irradiance and allows half the irradiance through.

Assume a one second long lossless unterminated transmission line.
Pour 1000 watts into it for one second. During the next second, we
disconnect the line from the source and you grab the two wires, one
in each hand. Then tell us whether reflected power exists or not.

Since an analysis of a 51 ft. G5RV-shorty would be interesting
to the group, I will do that, hopefully today.

Using 200 ft. of unterminated RG-58 on 440 MHz, the transmitter
sees close to 50 ohms and can deliver its full rated power into
the coax with no antenna. Therefore, I seriously doubt that your
question above is the "only *useful* question".

Cecil,

I am not quite sure what you are saying. But, I ran a SPICE simulation of
the following:
1V 1MHz source with resistor R0 feeding a 50 Ohm 250 ns transmission line
shorted at the far end. Independent of R0, in steady state the voltage at
the input end of the transmission line will be 1V. The effect of R0 is to
limit how long it takes to reach steady state. For R0 = 50 Ohms, it is one
cycle; for R0 = 500 Ohms, it is about 8 cycles, as eyeballed off the
waveform display.

Depends upon your definition of "best length". If "best
length" is defined as the length that provides the lowest
SWR at the source, zero is not it.

I guess I need to say this again. My take on discussions of conjugate matching in ham antenna systems is that it is a waste of time. If reflected energy is not allowed to reach the source, e.g. typical ham Z0-matched systems, the source impedance is irrelevant and doesn't affect anything in the system except for efficiency.

This post is guaranteed to get Cecil revivified. Here's a hint: quit thinking solely in
terms of power, that's for fellows who want to explain how it all works without going into
any of the complicated details. Get an undergraduate physics text that discusses
waves, and read it, or, better yet, take a class. Take all explanations you read in
amateur publications with a grain of salt. After you've done this, you still won't be
able to argue with Cecil, because that requires an extensive knowledge of the moronic,
unfair, and downright pathalogical debating techniques of which Cecil is a master.
But, it will be harder for you to fall for some of the crackpot ideas you're liable to
read on this newsgroup, and it will give you something to think about when sipping
your after-dinner port.

Does SPICE report the steady-state forward and reflected waves
or just the superposition of those two waves? We all know what
they look like when superposed. The question is whether the
identity of the forward and reflected waves disappear after
they are superposed. To the best of my knowledge, the very
existence of standing waves requires the existence of a forward-
traveling wave and a rearward-traveling wave.

I have asked for examples of standing waves void of rearward-
traveling waves and none has been forthcoming.

Like Hewlett Packard in their AN 95-1 publication? "Another advantage
of the s-parameters springs from the simple relationship between the
variables a1, a2, b1, and b2, and *various power waves*. ... The previous
four equations show that s-parameters are simply related to power gain and
mismatch loss, quantities which are often of more interest than the
corresponding voltage functions."

>Bandpass Filter to my set-up to minimize TV interference (even if I
>use a dipole, ref. my other post, "Re: Dipole/Balun? Commercially
>Produced Alternative?"

This sort of bandpass filter may not help matters much if at all, for
several reasons:

- If you're using a commercially-built transceiver, it almost
certainly meets the FCC's harmonic-suppression filtering rules right
out of the box - it has the necessary low-pass filters built into
its output section. You _might_ get some additional, useful
suppression via an external filter, but I suspect that the benefit
will be rather minor.

- These days, it's more usual for RFI/TVI to be caused by
"fundamental overload". TV sets usually have wideband tuner
circuitry, and they can be overloaded by strong RF signals outside
of the frequency range to which they're currently tuned. The RF
drives their first stage into saturation, and can wipe out
reception of _all_ channels. This cannot be avoided or treated
with a low-pass filter on the transmitter - it requires a high-pass
filter at the TV set's antenna terminals (and, in some cases, a few
ferrites on the power and speaker wires, to keep RF from leaking
into the set through these paths).

- If you're using pipes/radiators/gutters as part of your antenna or
counterpoise, you have to worry to some extent about the
possibility of rectification at metal-to-metal junctions. This can
cause the generation of harmonics (including some in the TV band)
even if your transmitter's output is perfectly clean. Eliminating
this problem requires finding the corroded metal-to-metal junctions
which are acting as rectifying diodes, and correcting the problem
(either isolating the metals completely, or "bonding" them more
securely with rivets, wire, contact-surface cleaning and
preservation, etc.

> The pipes/radiators throughout the building
>would be the counterpoise to the hot-wire ... not at all intended as a
>ground. I'm poised to do this rather quickly, minus the bandpass
>filter, which I need to order from HRO or AES.

Well, it's probably worth a try, but I suspect that the risk of
problems is nontrivial.

>So maybe I will try this out... Any last words about safety? Not
>blowing up the furnace room and heating oil tank? ;-)

Keep your transmit power relatively low. Fundamental overload and
other RFI/TVI problems seem to be less common at transmitter outputs
below 20 watts.

Just remember that the RF voltages appearing at certain points on your
antenna and "counterpoise" can be quite high, even at moderate power
levels. You may be exposing people to a significant risk of shock or
RF burns. If somebody gets "bitten" when they touch a radiator,
they're likely to be really irate with you.

I'd encourage you to run through the FCC's RF-exposure calculations,
assuming an "uncontrolled" operating environment, and very small
working distances between people and the antenna/counterpoise.

R + jX is a linear function. As your amp is probably push-pull
AB1 class, you could only ever obtain the averaged impedance of
two non-linear devices. Is that what you want?

80M is a bit lower than I expect, but not by much:referring to dBmax values. It probably picks up a dB or more at the high end of 75M.

It doesn't mean much to discuss 'average gain' values unless its an isotropic or (within a certain elevation range) an omni antenna. Sometimes vertical dipoles are described as having an 'average gain', but I haven't seen that used for horizontal ones:-)

The pattern is not bidirectional on the higher bands BTW... ar least that's what intuition tells me...

The reflected waves obey the laws of physics. The kicker is that we
don't know (and apparently cannot directly measure) the source impedance.
What the reflections can do is modify the designed-for load line through
superposition of the forward and reflected waves. Modification of the
designed-for load line is not desirable and, if unprotected, can cause
over-voltage, over-current, or phase problems.

OK, if we shine a flashlight at a mirror the light bounces back and what
ever is caught by the reflector will be reflected. Take away the reflector
and the reflection just keeps going. If someone can tell me what the hot
filament does perhaps I can understand what happens in the finals, or
whatever.

The hot filament provides a source of electrons. How many
electrons are emitted depends on the instantaneous voltages
on the other elements, the plate and grids. Reflected waves
have an effect on those instantaneous voltages but IMO,
there's not much sense in pursuing the "filament" line of
reasoning.

It's true in the case of transmission lines that there are standing waves and reflections but, unfortunately, this concept has somehow come to dominate and confuse the concept of matching a tranmitter to an antenna -- a generator to a load. Like in many areas of science, mathematicians and scientists often find convenient ways to mathematically describe and predict physical phenomenon that hinders, even misleads, the understanding of how it actually works.

If you leave out the complex part of impedences for the moment and think of 100 volt generator that has a 50 ohm internal impedance driving a 50 ohm load, current is 1 amp and the power dissipated by the load is 50 watts. There is also 50 watts dissipated by the generator's internal impedance, for a total of 100 watts dissipated by the entire system. Therefore, the "available" power for this generator is 50 watts.

Maximum available I^2*R power only occurs when the load impedance is equal to the generator's characteristic impedance, 50 ohms (do the math). Any load impedance higher or lower, ALWAYS produces less "available" power.

Herein lies one of the big problems with the "reflection" definition, conceptually. The generator (transmitter) is not a constant-power device. When a manufacturer says that it's XYZ transmitter produces 100 watts, it only produces (has available) 100 watts (after internal dissipation) into a 50 ohm load. Any other load *always* produces less available power, due to simple I^2*R laws. It has nothing to do with reflections or standing waves, although, mathmatically, reflection formulas accurately describe it.

A couple of examples using a 100 volt constant voltage generator and an internal impedance (RG) of 50 ohms:

1) Load (RL) = 50 ohms. Current = 100 / (50 + 50) = 1 amp
Power dissipated in RL (PL) = (1)^2*50 = 50 watts
Power dissipated in RG (PG) = (1)^2*50 = 50 watts
SWR = RL/RG = PL/PG = 1:1

2) Load (RL) = 100 ohms. Current = 100 / (50 + 100) = .667 amp
Power dissipated in RL (PL) = (.667)^2*100 = 44.5 watts
Power dissipated in RG (PG) = (.667)^2*50 = 22.25 watts
SWR = RL/RG = PL/PG = 2:1

3) Load (RL) = 25 ohms. Current = 100 / (50 + 25) = 1.34 amp
Power dissipated in RL (PL) = (1.34)^2*25 = 44.9 watts
Power dissipated in RG (PG) = (1.34)^2*50 = 89.8 watts

SWR = RG/RL = PG/PL = 2:1

Notice that the total power dissipated in all three examples is
different. The transmitter is NOT a constant-power source, but it's
also not a unlimited power source and has operational limits.

Therefore, what is commonly called "reflected power" is power that
never leaves the transmitter and is dissipated as heat by the
transmitter's internal 50 ohm impedance (if the transmitter's design
doesn't prematurely shut down first).

That's why I often resort to a signal generator with a circulator/load
to illustrate my point. That signal generator *is* a constant power
source.

> Therefore, what is commonly called "reflected power" is power that

You can mount an argument that if the source doesn't see its
source impedance, then there is a reflection at that internal
mismatch. But that's not what is commonly called reflected power.

When we talk about reflected power on this newsgroup, we are usually
referring to the forward power rejected by a mismatch between the
transmission line Z0 and the antenna impedance (associated with mismatch
loss). In a typical ham radio antenna system, the "lost" reflected power
is forced to engage in destructive interference at the tuner and thus
joins the forward power wave.

Hi Ian,

Perhaps in this immediate thread. However, I have demonstrated both sides coming to the same conclusions several many times, and one example as recently as within this last week.

This issue is not about being right, it is about ego foremost else why all the debate? Hank has asked a fairly straightforward question with rather simple terms he could accept as a compelling case. To this point (some 22 entries) that has been largely abandoned with each scribbler answering their own imagining of how to discover the philosopher's stone.

Well, the light emitted by tube filaments is irrelevant to the RF
function. I use light examples because light and RF are both EM
waves and a lot more is known about light than about RF.

What I am trying to say is that I don't know what happens inside
a transmitter. Under Z0-matched conditions, as with a tuner, I
believe that what happens inside a transmitter is pretty much
irrelevant. The transmitter sees its designed-for impedance and
that is essentially all that matters.

What I am willing to discuss in detail is what happens at a Z0-match
point (x) in an antenna system with reflections - something like the
following:

XMTR---51.5 ohm line---x---1/4WL 300 ohm line---1749 ohm load
100W --> 200W -->
<-- 0W <-- 100W

For these typical conditions, all voltages and currents are either
in-phase or 180 degrees out of phase at the match point (x), which
makes a power analysis the most simple analysis of all.

Richard, you are the only technical person I know of who
ever considered s-paramater analysis to be a secret or
mystery. It is one of the more technically popular methods
of analysis, ideally suited to transmission line analysis.

Hi Hank,

Round Two.

A short or an open certainly reflects. However, as you have observed
through your question, so does a poorly matched antenna; thus you must
agree that it presents neither a short nor an open. As such,
reflection is not confined to these two conditions.

We can display a condition where we have a 2:1 mismatch. This is
fairly commonplace as a consideration, if not as a reality. Here, the
reflected power is less than the total applied (some 12% if dead
reckoning is correct). That is, if the antenna presents a 2:1
mismatch to the power applied to it, nearly 90% of that power will
proceed to be radiated with a trivial portion returned to the source
(or the tuner). If we boost that mismatch to 10:1, that increases the
reflection substantially (let's call it 90% in this spirit of dead
reckoning) and naturally less is radiated. The math is quite as
simple as a balance ledger.

10:1 for a 50 Ohm source would mean either the load presents a Z of
500 Ohms, or 5 Ohms. From this you can see that we are approaching
either an open (hi-Z) or a short (lo-Z) and either perform the same
job of reflection - short of total reflection. As such, there is no
distinction to the power whether it encounters either, the reflection
ensues by virtue of the simple mismatch, not by the literal condition.
The computation of mismatch defines how reflective the interface is.

Old Son,

Lord Kelvinator would be saddened by such a dismissal of actually
delving into "knowing" by your meagre understanding that fails to
offer an actual value that it IS. Such superstition that dominates
this paucity would lead us to believe the Z is as slight as an angel
wafting past in a dream (would that be in English Units, or metric?).

Definitions by negatives is an amusing troll however. I do enjoy
participation in kind:

Let's see, the Z of a transmitter is NOT
a dead parrot, nor
five farthings, nor
10 inches, nor
a polka dot dress, nor
the gross national income of Lithuania, nor
the combined weight of all your dead white scientists.

I'm sure I missed a few.... ;-)

Hi Andrew,

You have asked an inescapable question that will lead to a deluge of scribbling commemorating the best attempts of Houdini.

There are several many methods to determine exactly what you want to know. The simplest and certainly the one that contains as much information necessary is called "load pulling." To even mention this time and bench proven method will result in hoots from those who would be the last to offer you a fixed answer; however, we shall proceed.

This requires that you have access to known, but non-standard value loads capable of sustaining the power you will perform your measurement at. This is not a trivial requirement. It also requires that you can in some way defeat your ALC which will attempt to offset the pull of the non-standard load.

It is simplicity itself that only demands you consider the elements of a Thevenin model and how to determine the model's source Z (or likewise, the Norton model's source Z). You will need a means to measure the voltage across the load, or the current through it. Even here, proportionality is all that is required as long as the Load is characterized and thus the tools can be rather spartan.

In the long run, this will mean you have to construct and verify your own non-standard loads. Take care that through your verification you confirm their value across all power applications (resistors are very susceptible to drift with temperature). You should also take care to insure that all paths and leads are as short as possible. Loading directly at the terminals will save grief of complex compensation math (and reduce introducing other errors). However, you can choose to employ remote loads if you take care to characterize the lines through which they are attached (this means you should be adept at the Smith Chart).

There is more to be said, but this enough to offer you a significant lead to find that, yes, the source exhibits nearly 50 Ohms (the common Ham transmitter running at rated power will fall between 30 and 70 Ohms) - as specified and designed.

what you are willing to discuss is irrelevent as it has nothing to do with
the original topic which was about what happens in the transmitter.

>
> For these typical conditions, all voltages and currents are either
> in-phase or 180 degrees out of phase at the match point (x), which
> makes a power analysis the most simple analysis of all.

that should read "For these specific conditions", those conditions are
hardly 'typical', they are a very exactly contrived example which makes it
easy to compare powers. thus making the proper analysis of currents or
voltages seem unnecessary. taking simple cases like this and improperly
generalizing them is what leads to the worst mis-conceptions and circular
arguments in this group.

Rich wrote:
> Cecil, any chance you can take one more look-see for me with EZNEC?
> How well do you think it will radiate on all the bands?

Rich, the easiest way for me to present a G5RV shorty version
is by listing the 50 ohm SWR at the ladder-line/coax junction.
The antenna is a 51 ft. center-fed dipole at 40 feet. The
series-section transmission line is Z0 = 400 ohms with a VF
of 0.9. I use Z0 = 400 because "450" ohm ladder-line is
usually closer to 400 ohms.

Freq. 50 ohm SWR for n' Length of "450" ohm line
6' 9' 12' 15' 16' 19' 40'
7.2 31 16 5.8 *2.2* 2.7 8.3 >100
10.125 16 23 29 33 34 34 *1.9*
14.2 70 53 32 13 8 *1.2* 55
18.14 51 18 *1.5* 13 23 57 19
21.3 22 *1.5* 19 61 74 98 61
24.95 *1.7* 30 76 94 88 48 6
28.4 26 30 17 3.3 *2.0* 12 31

The lowest SWRs are highlighted like *n.m*. It appears
that a fixed length of about 17 ft. will be a good
performer on the harmonically related bands, 40m, 20m,
& 10m. Varying the series section length from 6' to
19' would allow covering all HF bands except 30m. A
51 ft. dipole is not a good length for 30m and requires
40' of "450" ohm line to resonate it close to 50 ohms.

IMO, any 50 ohm coax SWR above about 10:1 is unacceptable
for ordinary coax (depending on frequency).

Uhhhh Dave, the original topic is the Subject: line. If anything,
what happens inside a transmitter is the irrelevant subject since
appreciable reflections hardly ever reach the typical ham transmitter.

No, those are typical conditions, where the ham radio antenna system
is tuned to a Z0-match by a tuner, either external or internal. It is
not a "very exactly contrived example" at all. It is absolutely typical
of any ham radio installation where the final amp sees close to a 1:1 SWR
and that is the great majority. At the Z0-match point at the input of
every properly tuned transmatch, the voltages and currents are either in
phase or 180 degrees out of phase. If you don't know that, it is no
wonder that you label my power analysis stuff as "contrived".

>Hank WD5JFR

Hi Hank,

Well I see in correspondence following this as "replies," that they
are far from satisfactory. All part of the arcana that precedes the
convolutions of math you would have had to endure.

The abandonment of this lead is simply a matter of Cecil's lack of
experience in the metaphor of light.

To answer your question above. Removing the reflector is unnecessary
as it is part of the initial condition and has nothing to do with it
serving as the correlative to a tuner that you want to remove from the
argument (which is a perfectly acceptable imposition of conditions).

Your question also goes to the heart of the matter. We begin with a
hot filament which emits radiation (and yes, no reflector is required
so we will skip that as one of your conditions). The amount of
radiation is directly correlated to the amount of heat. This will
simplify matters, but in the end it will yield a failure of metaphors
(which always occur if you cannot bridge the logic).

The radiation strikes a reflection (immaterial whether complete or
partial) and that portion which returns, impinges upon the filament,
the source. The filament absorbs the power, which in turn raises its
temperature (everyday experience proves the heat of such radiation).
This will, in turn, cause a higher radiation (given the quid-pro-quo
of heat and radiation). In a sense, this means the reflected power is
re-radiated. The confirmation of this is that if you achieved full
reflection, you then define total insulation of the radiation (no heat
escapes) and temperature rises accordingly, and this may lead to
catastrophic failure of the filament (a very bright illumination if
you could see it, and consequent fusing current - electric kilns use
this principle but tolerate the current by under rating the source).
You can imagine the correlative to transmitter failure for the same
conditions.

The failure of the metaphor? RF is not heat (common light is) and the return of power to be rendered into heat does not result in a higher RF output.

I will anticipate the sophomore's comments that RF reflections do not become heat, in and of itself:

The returned power (either through wave mechanics or lumped circuitry) must result in either a higher potential across the source, or a higher current through it. Elevated potentials yield the everyday experience of an arc (heat). Elevated currents yield the everyday experience of current density through the same element (much like the filament of our metaphor - heat). One failure mode comes with the peak power snap, followed by the muttering of "Oh Shit!" Or it comes through the more progressive thermal runaway, followed by the muttering of "what's that funny smell?"

It shows the composite voltage waveform, and the net current. Exactly what a
Bird wattmeter would do. Of course the Bird only shows you steady state,
Spice (SWCAD) swhows how you got there.

That's not what a Bird wattmeter does. A Bird wattmeter possesses
a directional coupler. SPICE apparently does not. Is it possible
to add a directional coupler to SPICE? If you know the Z0, the net
voltage/current magnitudes/phases, it should be possible to use
phasor addition/subtraction to obtain the forward and reflected
components, just like the Bird wattmeter does.

RE: Concept below

However this is not an accurate model of a transmitter.

For an example, take an old Heathkit DX-100 generating a measured 180 watts of CW RF into a matched 50 ohm load. To do this, it does NOT also dissipate 180 watts of RF into some "virtual" internal RF load in the DX-100. In fact, the PAs and power supply in the DX-100 could not produce a total RF output power of 360 watts without exceeding their ratings.

The dissipation in the PA is essentially related only the DC to RF conversion efficiency of the PA, which in this case probably is about 75%, max (Class C). So a PA input power of about 240 watts DC is required to produce 180 watts of RF output power. The other 60 watts of plate input power is converted to heat by the PA tube anodes.

The entire RF output generated by the PA stage is applied virtually 100% to the output connector. How much of that is absorbed by the load connected there is a function of load SWR and system losses.

- RF

Another acquisition from the Belton hamfest that I'm looking for info on. It's engraved "HIGH IMPEDANCE PREAMPLIFIER MODEL AW-203-1" EO Electro International, Annapolis, MD. Someone printed by hand on it; "150 KHz - 12 MHz". It has a four position switch labeled Off, Recharge, Rod, Loop and an output BNC. It's been fitted with what looks like a non-original whip. There's no provision for a loop or rod and I'm guessing that there was a rotary joint to replace the loop. Any info appreciated. Pix posted to alt.pictures.binaries.radio.

What does scattering have to do with antenna systems with
reflections???? Maybe you should download the HP AN 95-1?
It's available at:

http://www.sss-mag.com/pdf/hpan95-1.pdf

From _Fields_and_Waves_in_Communication_Electronics_ by
Ramo, Whinnery, and Van Duzer. "11.09 Scattering and
Transmission Coefficients ... This article introduces two
of the *most* useful (two-port analysis) forms based
on wave quantities." This is a (c)1965 book, a later version
of a classic fields and waves (c)1944 book by Ramo & Whinnery.

2650. Measuring output impedance

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-23 20:42:59 UTC
From: Lord Snooty <bonzo@dog.com>
Message-ID: <n18sc.7505$be.1145@newsread2.news.pas.earthlink.net>
Source record: 94805

Wise words. The true load-pulling technique advocated professionally uses a known model of the output stage using S parameters. Yuk. Not for this soldier. I'd rather sniff underwear in a geriatric clinic thank you. Whatever one did in this direction, as an amateur, would doubtless be either wrong or so inaccurate as to be not even wrong as Dr. Pauli was wont to say.

The amp is single-ended out of an MRF136, so I presume it's Class A. The amp's designation is H-10 (I bought it surplus). It's rated at around 15W, 0.1 - 30 MHz. The circuit diagram shows no hint of current limiting circuitry.

If one is serious about proper design of a matching network - a network, I might add, which attaches *directly* (near as dammit) to the Tx output - then one is all at sea without a proper knowledge of source impedance. See my comments in the other thread about this.

I tried to use a technique advised by K7ITM to measure source impedance (R + jX), and it produces a negative value of R by calculation. This is the technique, based on a load setting of (r + jx) ohms. And once again, there is no cable, folks. And it wouldn't matter if I did have a few inches of it either.

1. Determine X.
a) Set r ~= R based on a best guess (which would be R=50 ohms nominally in many systems).
b) Monitor the voltage, current, or power in the load (r).
c) Adjust (x) to maximise the monitored value.
This setting corresponds to x = -X, and we have determined X.

2. Determine R
a) Leave x = -X set as in step 1,so now the circuit is pure resistive.
b) Monitor the voltage across the resistor.
c) Set r to R(nominal) plus and minus a small percentage, and measure the monitored voltage at both values of r.
The voltage across r is given by
V/V0 = r / (R + r)
Solving the 2 simultaneous equations to eliminate V0 shows that R is determined by the equation
R = r1*r2*(V2 - V1) / (V1*r2 - V2*r1)

My problems
---
1. My measurements of V1,V2 lead to the inescapable conclusion that the above model fails, because the calculated value of R comes out negative.
Let us assume that we set (r2 > r1) and we obtain (V2 > V1), which is predicted from the model, and is also the case for my measurements. Under

these conditions, a negative value of R can only be obtained from the equation if V2/V1 > r2/r1, which in my case is true.
I undertook a full (and rather exhaustive and tedious!) calculation of the expression for R when the value of (x) was not set correctly to -X, thinking that perhaps this was the cause of the discrepancy. It turns out in this case that, if the calculated value of R is negative, it has nothing to do with the setting of (x), and depends ONLY on the condition V2/V1 > r2/r1. Since we know that the actual value of R cannot be negative, this implies a failure of the model.
How then can the model fail? Since we are maintaining frequency constant, any collection of resistances and reactances, however complicated, can be modelled as (R + jX), so it cannot be that. The only assumption left to question is the constancy of V0, and this is what the failure must be.
This leaves me with more questions than answers, because the way forward is now completely unclear.

2. I should also mention another, less serious, problem I had, and that is with the determination of X. The value of (x) I determine from measurement would be expected to be constant at a given frequency. It is in my case not so. The derived value of X appears to depend on
a) the power level setting of my amplifier
b) the value of (r) I set in the circuit when determining X.
Quite probably this second problem relates to the first problem's identification of the failure of the model, and can probably be subsumed under that category.

Best,
Andrew

Source record: 94806

Sorry everyone, but I just retested with no cable and the results I obtain are precisely the same. The coax cable was only 26" long anyway.
So forget about that transmission line stuff. It's irrelevant here. What I want to know is why the VSWR indications are the way they are.

If anyone's interested, I can email a small spreadsheet that deals with this simple circuit (V0->R->jX->r->jx) and allows you to set
a) R,X and r, and vary x
b) R,X and x, and vary r.
I plot side by side on the two corresponding graphs
- modulus of total load voltage
- modulus of load resistor voltage
- modulus of load reactance voltage
- power dissipated in load resistor
- VSWR between source and load
- "conjugate VSWR" between source and load.

One more time with feeling -
What I want to know is why the VSWR indications are the way they are.

Best,
Andrew

Back a dozen years ago, or so, Mr. Bruene tried to 'ping' a final amp with a slightly off-frequency signal to ascertain the output impedance of the amp and he published his results in QST. His apparent error was that he didn't do it at the frequency of operation of the amp and he didn't know what the 'Q' of a final amp really is. There has been a running argument ever since, probably best documented in QEX magazine. There are basically two sides to the argument.

1. If load-pulling causes a falloff of power on each side of the operating point, then the system is conjugately matched. That conjugate match includes such things as non-dissipative resistances.

2. Conjugate matches do not exist in a typical amateur system.

Brilliant minds have been trying to prove one or the other and both sides (IMO) have failed in that proof. There is no final, definitive proof of either position. If there was such, there would be no argument. That's why we cannot answer your question. The picture is further clouded by a definition. If reflected energy makes its way back into the final amp, it was never generated in the first place, by definition.

probably because the meter is not measuring what you think it is. remember,
vswr meters are meant to be showing what the vswr is in a transmission line
of a given characteristic impedance. they are not impedance meters, nor are
they proper power meters even though they are often calibrated in watts...
they are only accurate in the specific characteristic impedance system they
were 'calibrated' for... and then only roughly in most cases. if you want
to make proper measurements give up on the vswr meter and measure the
voltage or current with an oscilloscope or properly calibrated rf voltmeter.

Hi Andrew.

Specification sheets respond to these issues quite well. The MRF136
is a 400MHz device, normally offering 15W max with about 16dB gain at
28Vdc (although rated higher) in a class A configuration (showing
about 60% efficiency).

As would be expected, it covers a lot of turf. In the HF, the output
Z runs easily near 50 Ohms in push-pull circuit configurations;
otherwise it is simpler to describe it in the teens to tens of Ohms
across any number of variables you do not disclose (like frequency,
the actual configuration, additional interface components). 1 - 10
MHz does not bode well towards the best implementation of an UHF
device.

Load pulling is vastly simpler than S-parameters (also specified in
the data sheets for this device, down to 1MHz), why you want to marry
the two is a mystery.

here is the original:

I know that any power not dissipated by an antenna is reflected back to the
transmitter. Then the transmitter "reflects" this reflection back to
antenna, ad nauseum until its all gone. I also know that a short or an open
is required to reflect power and I'm searching for which it is, an open or a
short. I'm inclined to think it's a virtual open but I'm at a loss to
understand that and I wonder if someone has a good explanation or analogy
and some math wouldn't hurt.
tnx
Hank WD5JFR

obviously not about what is going on at some contrived transmission line
joint.

Henry, the trouble is nobody can understand your questions. This is because a "conjugate match" is not relevant. And that's because the internal impedance of the transmitter is an unknown quantity.

The sole purpose of the so-called SWR meter is to indicate whether or not transmitter is loaded with 50 ohms.

Can anyone suggest what else it USEFULLY indicates? What else does anyone need to know?

My original question nor any subsequent questions included or even hinted
"conjugate match." SWR was not in the original question either but later as
it applies to ghosting or smearing transmitted TV pix. Again is it an open,
or short and if not what is it or can't it be explain becasue no one knows?
I guess may Sunday is a day of relaxation for minds that know!

Hank, You're preaching to the choir, asking me that question.
I don't like that definition but if you poll the gurus on this
newsgroup, most will say that reflected power that is incident
upon the transmitter was never generated in the first place.
(Never mind the ghosting that they can see with their own eyes.)

Lots of steady-state ills can be swept under the rug by assuming
nothing but fixed frequency sine waves with zero modulation. A
guru's answer to you question is that "ghosting is not steady-
state". :-)

A laboratory bench setup is simpler than a calculator and a couple
of sheets of paper? Egads Richard, s-parameter analysis was invented
in order to make things "vastly simpler" - and it does!

RE: Quote below

Actually, it depends upon where that high SWR physically is located.

A dummy load with a 1.3:1 SWR connected directly at the tx output connector will not produce a visible ghost in the demodulated TV picture.

A 1.3:1 antenna SWR at the far end of more than about 500 feet of otherwise matched transmission line connected to that same transmitter WILL produce a visible ghost.

Are you saying that the original subject was wrong?

> of course it is contrived. no one uses loads of those exact impedances, or
> lengths of coax like you do.

Dave, have you ever heard of an example? What I posted is one
easy-to-understand example of virtually an infinite number of
possible examples of a Z0-match. If you like, here is another
example of a Z0-match:

XMTR------tuner---unknown length of feedline---unknown load
100W-->
<--0W

There is a Z0-match at the input of the tuner. All the voltages
and all the currents are very close to in-phase or 180 degrees
out of phase at the input of the tuner. Do you have the balls to
assert that the above configuration is "contrived"?

THE GREAT MAJORITY OF AMATEUR RADIO ANTENNA SYSTEMS ACHIEVE CLOSE
TO A Z0-MATCH!!! That means all the voltages and currents are close
to being in phase or 180 degrees out of phase. I'm sorry that technical
fact hairlips you. Since your hidden agenda is hidden, I can only
guess what it might be.

It usefully indicates the vector sum of two voltages
proportional to the net voltage and net current. It
also usefully indicates the vector difference of the
two voltages proportional to the net voltage and net
current. Those are extremely useful indications for
the initiated. I agree it is not very useful for the
uninitiated. I trust that doesn't include you.

I'm a tad confused about this "reflected power" thing.

I've heard some statements that reflected power is something like shining a light at a mirror.

But if the power is truly reflected, would not this be an easily quantifiable thing?

Let's say a signal goes down a wire, "sees a mismatch" and is reflected from the end. IIRC, light travels around a foot in a nanosecond. So if you have an 80 meter dipole, and send out a mismatched signal, should not you get the reflection back to the source in a quantifiable time? That the signal isn't going quite that fast is only a measurement help. The reflected signal would be delayed significantly, no?

I can easily visualize the idea that an antenna needs to be matched to a transmitter, either through the antenna's natural impedance, or through a network that makes it look like it is. Deviations on either side of the impedance will cause problems, just as they will with other systems that are expecting a particular load and getting something different. But the idea of signals being actually reflected seems hard to swallow.

I'm a real dilettante in these matters, but why would a signal be reflected if the impedance was incorrect, and not if it was correct?

Possibly I'm saying some pretty stupid things here.

Dunno why, but that's just the way it is. To see for yourself,
feed a 75 ohm TV through 1000 ft. of 75 ohm coax. Then feed
the same TV through 1000 ft. of 600 ohm ladder-line. How do
you explain no ghosting in the first case and lots of ghosting
in the second case? Seeing is believing.

Sorry Henry. I confused your query with what's going on in another thread.

Short circuits and open circuits result in reflection coefficients of -1 and
+1 respectively.

Reg

I made note of this in a thread I just started. Is this a good analogy?
Certainly the signal goes out, hits something and then comes back.
Wouldn't this scramble the signal by some definable amount in an antenna?

All we have to do is get an antenna that is 186,347.3233361 miles long.
Or would that be 122,989.233401 miles?

At any rate, the answer should be pretty easy to verify by using a very
long but practical sized antenna. Anyone done that?

So if we had an infinitely long antenna, would the power put into it
last forever?

They make an instrument called a Time Domain Reflectometer,
you hook it up to transmission lines and it sends out a pulse
and times how long it takes to get back.
The time it takes, reflected pulse polarity, and height says a lot about the
line.
Used for finding faults on telco/cable lines.
Does the same thing with RF lines.
Matched well, no pulse, but you can even see connectors on some of these
TDR's
Googleit, too

It's true that even a simple DC battery circuit can be described in terms of incident and reflected power, SWR, and reflection coefficients, but that's very unrealistic when trying to conceptually understand what's going on.

I suppose a point that I'm making is that understanding how to match a source with a load doesn't have much to do with reflections and standing waves although, again, it can certainly be described (unrealistically) that way.

Take the case of a transmitter and an antenna connected together with a two-port black box between them, and that black box happened to contain a transmission line. That unseen transmission line has standing waves and reflections (assuming a mismatched condition), losses, etc. all contained within the box. However, the transmitter only sees a steady state complex impedance when looking into the box (at a single frequency). Obviously there's some conjugate matching that needs to take place for maximum power transfer, but there are no reflections or standing waves involved outside the box -- unless transmission line stubs are used for matching.

In short, transmission lines have reflections and standing waves, and as a "black box" they affect how the load is seen by the source. But extending the power reflection concept outside of that black box only confuses things, even though it works mathmatically.

Of course, but the point is that there exists energy as power, ExH,
in the reflected wave. If there is no energy in a reflected wave,
radar wouldn't work. Anyone who says there is no energy in a
reflected wave is just pulling your leg.

Anyone who has ever used a TDR on a mismatched transmission line.

It would have a feedpoint impedance of around 600 ohms and I
don't know how long it would have to be to eliminate reflections.
A terminated rhombic comes close to the characteristics of an
infinitely long antenna.

Fascinating stuff! Why don't we use them more for ham radio? this page:
http://www.epanorama.net/circuits/tdr.html even has a diagram for a
homebrew pulse source and diagrams for hooking up same to an
oscilloscope. While not giving SWR, it would show up any connector
faults and crimps in the cable.

That's a steady-state shortcut which assumes pure sine waves that
don't exist in reality. Please don't confuse steady-state shortcuts
with reality. Noise and modulation cause the "steady-state complex
impedance" not to be steady-state at all. Many will say it's close
enough, but one cannot understand reflections by assuming an un-
varying steady-state.

In a TV system with ghosting due to reflections, the unvarying steady-
state condition doesn't exist. In fact, when you assume steady-state
conditions, you eliminate ghosting, at least in your own mind. In
reality, steady-state doesn't really exist because of random noise
and unpredictable modulation.

Mike,
If you really want to see reflections, forget all about sine waves and steady state. Connect a pulse generator with any output impedance, except 0, to a piece of coax. Monitor its output with a scope. Now set the pulse generator to put out pulses whose width is less than the delay time of the coax. Use any convenient rep rate for the pulse generator (1 KHz is good), and you will easily be able to tell forward going pulses from the reflected. You will also be able to tell how the far end cable termination determines how much of the pulse is reflected, and what their polarity is. You do *not* need a storage scope.

This should be fun, Tam. I have some known bad cable on a mobile
antenna. I'll have to add some more cable to it because it is so short,
but it will be fun to see how close I can get to the crimp in the cable.

S-parameters are supposed to work best on small-signal analysis, where
everything is fairly linear. In this case, the MRF 136 is a power fet and
Motorola
says you can use s-parameters as a first approximation. In the data sheet, they
provide a list
of common source scattering parameters from 2.0 Mhz up to 800 Mhz. I suppose
that's useful to someone familiar with s-parameter techniques.

But its not free. If you tap it, it won't be there to re reflect. So, I think in the steady state you have changed the load impedance. BTW, (not a joke or sarcasm) Have you heard of Zero Point Energy? They calculate there is something like 10**26 Joules in a cubic meter of empty space.

The data sheet doesn't say it gets 60% efficiency in a class A
configuration. It just says, under one bullet, that "Efficiency = 60%."
Further down the column it says, "Ideally Suited For Class A
Operation."

There is a Motorola ap note that agrees with what Richard is saying. To
paraphrase it, if the the DX100 had an output impedance of 50 Ohms, then the
overall efficiency would be 37.5%.

Therefore, should work well on transmission-line analysis, where
everything is linear.

Moral: don't use it up, just use a negligible portion for measurement
purposes. A Bird wattmeter consumes very little actual power.

> BTW, (not a
> joke or sarcasm) Have you heard of Zero Point Energy? They calculate there
> is something like 10**26 Joules in a cubic meter of empty space.

Yes, some people think that is the energy being measured, off and on,
in the cold fusion experiments. The question is: If one taps into
the energy being used to support the structure of space itself,
what happens to that space structure? IMO, space is the result of
the annihilation of matter and anti-matter in the early universe
and certainly still contains that annihilation energy.

I haven't been here terribly long, maybe 6 weeks, but I have noticed that your comment applies to around half of the threads longer than 4 or so comments.

A better ratio than many newsgroups, and people seem to have a sense of humor, which a lot of other newsgroup's participants decidedly do not. So, all in all, it could be worse.

Hi Chip,

Yes it does help to hear it works reasonably well when other circumstances limit the options. I can't for instance squeeze more long dipoles up, but I could try one of the T2 varieties someday. Since the dipole I now have works across many bands well with a tuner, the B&W could never replace it, but it might augment it someday.

Cheers and thanks,

An SWR meter does NOT usefully indicate the vector sum of two voltages or the vector difference between two voltages. I've never seen a meter with such scales.

Even if it did, of what possible use would it be to anyone who is already reliably informed his transmitter is loaded with 50 ohms.

Is there a human being alive today that questions that if the other
party lost while getting a majority of the votes, we wouldn't be looking
at a massive attempt to abolish the electoral college?

And there was a lot more going on there than the "official" results.

Hi Guys,

I trust both of you appreciate the difference between a vaguely described system and trying to fit a spec sheet to it. Far easier to proceed direct from one or the other, but making a fit between the two is like stepping from one boat to another with a high chance of standing on neither.

>shining a light at a mirror.

Hi Mike,

It is more like shining light against a dirty window. Very few,
natural occurrences of reflection are total (make that zero if you go
out enough decimal places).

> But if the power is truly reflected, would not this be an easily
>quantifiable thing?

The concept is easy, the fulfillment (measuring it) proves to require
you meet exceptional circumstances.

> Let's say a signal goes down a wire, "sees a mismatch" and is reflected
>from the end. IIRC, light travels around a foot in a nanosecond. So if
>you have an 80 meter dipole, and send out a mismatched signal, should
>not you get the reflection back to the source in a quantifiable time?

Yes, I presume you can do the math.

>That the signal isn't going quite that fast is only a measurement help.
>The reflected signal would be delayed significantly, no?

Ah, now you get to the nut of the matter. Significant? That is in
the eye of the measuring device. Would a Simpson 260 catch it? Not
on your life. Would a 100MHz O'Scope? With a rise time of several
nS, compare this to your computation from the math I presumed you
could do. Use a long enough transmission line with enough voltage
driving it, and probably so. You will still need to do more
computation to render the reading into a conventionally expressed
answer.

> I can easily visualize the idea that an antenna needs to be matched to
>a transmitter, either through the antenna's natural impedance, or
>through a network that makes it look like it is. Deviations on either
>side of the impedance will cause problems, just as they will with other
>systems that are expecting a particular load and getting something
>different. But the idea of signals being actually reflected seems hard
>to swallow.

It is all a matter of experience and the time scale you are typically involved with the phenomenon. Nanosecond phenomenon barely registers in the HF scale as a time distinctive characteristic (that is, to distinguish reflections as such, it is more convenient to think of these problems in terms of lumped circuit elements).

> I'm a real dilettante in these matters, but why would a signal be >reflected if the impedance was incorrect, and not if it was correct?

This is more a matter of degree. When you look through a dirty window you don't really notice the dirt, or the reflection of your face looking through the window if you are looking at something interesting. The degree is found in your attention. If you examine this closely, you begin to see the dirt (attenuation) and your reflection (mismatch) and if you took the window away, you immediately appreciate the difference (no attenuation, no mismatch). Tilt the window to eliminate the reflection (of your face that is), and wash its surface, and you will note no difference between the window being, or not being before you and the object you are looking at. This is a common trick of department store windows that face lit streets.

> Possibly I'm saying some pretty stupid things here.

Actually the answers have been quite competitive in that respect.

> a directional coupler.

Sort of. I have built circuits that subtract out the transmitted signal,
leaving the received signal.signal. The Bird is cruder than that.

>SPICE apparently does not.

I was driving it with a sine wave, but did a transient analysis. The whole
point is it does not have to know about reflections. It calculates the
waveform by using the same rules that are used to derive standing waves and
reflections.

> Is it possible
> to add a directional coupler to SPICE?

I have built a SPICE model of a Kenwood power/SWR meter (Have better
schematic than for a Bird). Actually, an idealized version that is not
physically realizable; I did this on purpose. Clearly shows what the
limitations are. Interesting thing is that there is information present that
no SWR meter that I know of displays. For an SWR other than 1:1, you can
deduce whether RL is bigger or smaller than Z0 by comparing two voltages.

If you know the Z0, the net
> voltage/current magnitudes/phases, it should be possible to use
> phasor addition/subtraction to obtain the forward and reflected
> components, just like the Bird wattmeter does.

But there is only one voltage sample, which is the sum of Vf and Vr. There
are two current samples, but they are exactly the same, only one is 180
degrees out of phase due to looking at the opposite end of the current
transformer.

Here is what happens. Say you want a meter that shows 100W full scale when
feeding a 50 Ohm load. That is 70.7 V and 1.414 A. In the "Forward"
direction this leads to

100 = 70.7K1 + 1.414K2

In the "Reverse"direction, we know that Pr=0, so

0 = 70.7K1 - 1.414K2 (The minus sign comes from reversing the current reading).

You have 2 equations, so you can solve for K1 and K2. You know it can't *really* measure power, because there is no multiplier. Just like the Bird, it *adds* (vector wise) voltage and current.

> the vector difference between two voltages. I've never seen a meter with
> such scales.

That's the way a Bird wattmeter works. The vector sum of two
voltages is the forward power on the scale. The vector difference
of those same two voltages is the reflected power on the scale.
One voltage is proportional to the net voltage. The other voltage
is proportional to the net current.

> Even if it did, of what possible use would it be to anyone who is already
> reliably informed his transmitter is loaded with 50 ohms.

In addition to my 50 ohm SWR meter, I have 450 ohm and 300 ohm
SWR meters, Reg. They indicate the forward/reflected powers and
SWR on the antenna side of the tuner which I find most helpful.

Exactly, and if you work out the math, you will find it yields
a meter deflection that can be calibrated in watts of forward
or reflected power.

In your example, assume that 70.7v yields a 5v sample and 1.414a
yields a 5v sample. If they are in phase, 10v will indicate 100
watts forward and zero volts will indicate zero watts reflected.
If they are not equal and not in phase, their sum still indicates
forward watts and their difference still indicates reflected watts.

2711. Goodness of ground Radials

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-24 05:02:49 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <c8rvlp$il1$1@sparta.btinternet.com>
Source record: 94766

We are accustomed to using the *number* of radials as a measure of the goodness of a system of shallow-buried or surface-laid radials. But what really matters is the resistance to Mother Earth as is effective at the system center or off-center as the case may be.

We are familiar with associating soil resistivity data with 'goodness' of the soil or the terrain.

Forgetting all about what the regulations may specify about commercial transmitting stations, what are the ranges of ground electrode resistance which amateurs consider to be excellent, good, average, poor, awful. Or perhaps some other descriptions.

The following ranges are suggested:

Excellent : 2 ohms or less.
Good : 2 to 5 ohms.
Average : 5 to 15 ohms.
Poor : 15 to 50 ohms.
Awful : Greater than 50 ohms.

Are these in the right ball-parks? Depends on frequencies of occurrence.
What do you think?

Anyway, it makes a change from circulators and S-parameters at SHF.

Reg, G4FGQ

>S-parameters are supposed to work best on small-signal analysis, where
>everything is fairly linear.

Hi All,

Tom's implication (S-parameters don't fit to power amps) is supported
by a simple comparison of another UHF transistor, 2N3948:
by S-param as measured
input R 9 Ohms 38 Ohms
input X 12nH 21pF
output R 199 Ohms 92 Ohms
output X 4.6pF 5pF

S-params may be useful for comparing devices, but are inadequate for
power application design - unless, of course, you can tolerate 400%
error and inverted reactances.

The actual subject of the s-parameter analysis was a linear Z0-match
network point, not an amplifier, so your statements are irrelevant.

There are uncharacterised components surrounding my MRF136, and I'd rather determine their lumped behaviour with the transistor than unsolder them one by one and try and predict the answer. But that's because I think it's possible to determine what's going on. One reason I *don't* think this is the following little bench test this afternoon - with the load jammed directly on the amp output; no cable, no VSWR meter.
At 8.000 Mhz and a load consisting of 50 ohms carbon 10W 10% in series with a capacitance trimmer bank, at an output power level of about 2W, a load capacitor value of 250 +/- 10pF (-j80 ohms @ 8 MHz) was found to produce a minimum in the total voltage across the load. Also, as capacitance was increased over the range 100-700pF, the voltage across the load resistor increased monotonically.

The latter is easy to explain (it means the source reactance is positive, and smaller than +j28.4 ohms), but the former is beyond my ken.

Best,
Andrew

Hi Andrew,

You got me confused too.

Is the "load" the resistor, or the resistor-cap combination when you
measure these voltages?

You describe a voltage minimum across the load for a cap setting of
250pF; but you also maintain that the voltage across the load
increases for the variation in capacitance from 100 to 700pF which
contradicts the first measurement.

Further, the construction of a high power semiconductor does not lend
itself to supporting inductive reactances (the junctions are quite
manifestly capacitive in structure). By specification the device is
characterized as exhibiting 27pF @ 1 MHz (for 28Vdc although there is
not much variation until below 10Vdc). There are a world of other
variables to consider, but none portray inductance within the device.
This alone should provoke you to re-examine your premise.

i use one regularly in my station here. most people don't use them because
a simple swr meter is adequate for testing most antenna./feedline
combinations in use by amateurs.

news:<c8rvlp$il1$1@sparta.btinternet.com>...

Hi Reg,
unmistakably, the number of radials is not the only measure of the
goodness of RF grounding. Their length related to the working
wavelength is certainly significant as well - imagine 120 radials 1
meter long each at 160 m ... The soil structures underneath and beyond
the radials play an important role, too. An analysis of this problem
is given in the famous book by John ON4UN.

> The following ranges are suggested:
>
> Excellent : 2 ohms or less.

> Awful : Greater than 50 ohms.
>
> Are these in the right ball-parks? Depends on frequencies of occurrence.

IMHO they are right at shortwaves. One problem: how to measure the
grounding resistance simply ? It should be measured at the working
band. Measurements with a ground resistance meter may apply to static
and lightning protection (which is VERY IMPORTANT, too), but not to
RF.

SWR ghosts are usually smear because the transmission line is short and the
displacement fo the image is small compared to object reflection shost which
have a greater image displacement becasue the reflected signal travels over
a greater distance.

2721. Re: Reflected power (TV ghosts)

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-24 12:50:37 UTC
From: Richard Fry <rfry@adams.net>
Message-ID: <2he9chFb98nuU1@uni-berlin.de>
Source record: 94676

RE: TV Ghosting (quotes below)

To elaborate, the visibility of a ghost image in analog TV systems is related to the magnitude, phase and time displacement of the RF reflection that produced it as compared to the original, or non-reflected waveform.

The round-trip transit time from the TV tx output to the mismatch in its antenna system will determine the time displacement of the ghost, at the rate of 1 microsecond of displacement per ~490 feet of distance between the tx and the reflection plane (vp = 0.997c).

The visible part of a TV image is scanned onto the display screen at a horizontal rate of about 1 line per 50 microseconds.* An internal reflection from a transmit antenna connected to the tx by 1,000 feet of transmission line will create a ghost image ~1 microsecond after the main image -- or ~1/2" to the right side of it in a 25" wide picture. As the narrowest vertical line that can be viewed on a display using a 4MHz video bandwidth is a bit less than 0.35 microseconds wide, a ghost image of it displaced by 1 microsecond is clearly and separately visible on a 25" wide display, and will not appear as a "smear" of the main image.

Ghosts also can be produced by external reflections of the radiated TV signal from buildings, large signs, etc. Often these ghosts have much greater displacement from the main image than those that can be transmitted from reflections in the TV transmit antenna system. This is the result of the greater transit time for those reflections w.r.t. the direct ray, that are common for reflecting and scattering surfaces where located in the propagation environment.

Reflections with "short" time displacements are more difficult to resolve separately as ghosts, but still affect and limit the visual quality of the TV image. Reflections 40dB or more suppressed from the main image have no practical, visible affect on it -- regardless of their time displacement.

R. Fry, RCA Broadcast Field Engineer 1965-1980

Well, I found it interesting that the R7 is a 3/8 wave antenna, not a
1/2-waver. Which means radials might work as well as those 2-meter
whips/decouplers sticking out at the base.

Funny, I've never seen Cushcraft refer in their ads to their designs
being "1/2 wave." Maybe that's just a myth somebody started...

There is a third case, which will cause the same results. Namely, the effect of passing the signal through a filter with a nonlinear phase characteristic.

on yagi's and other antennas with matching networks you usually just see the matching network. i use it the most on my beverage antennas which kind of look like long transmission lines and also to find faults in transmission lines themselves. with 25 lines or so ranging from about 50' to 500' or so it makes for a quick check... especially in winter.

Rich, coax can be a consideration when loking at multi-band tuning. There are a number of books out threre with the formulae.

As to baluns, you might not even need one. Many hams mistakenly include baluns automatically in ther antennas, and introduce problems. I would suggest you try a dipole with no baluns, and only add one if you discover TVI or RFI problems.

Following a query, Guru's feel an urgent desire to display their knowledge about S-parameters, Time domain reflectometers, Circulators, and High power UHF TV transmitters.

As a consequence, the unfortunate original questioner, with his solitary 1.8 to 30 MHz SWR meter, is entirely forgotten about and remains suspended in mid-air.

As I have said many times here, The B&W antenna is for those that need
it not those who can/need/want to use other means of connecting with the
ether. It is definitely not the most efficient means of wireless
communications but it is definitely fool proof in operation.

RE: Quote below.

The on-channel TDR pulse performance of a narrowband antenna can be seen by controlling the RF bandwidth and spectrum span of the test process to fit the application. The pulse (ping) itself is modulated onto an RF carrier set at the operating frequency.

Not practical for most hams, but very useful in evaluating and optimising TV transmit antenna systems.

If anyone is interested in seeing a jpg of such a measurement, pls e-mail me directly.

Oh boy. This is one of the reasons our country is such a mess. People
do not know the difference.

To put it _really_ simply. In a true democracy the population would get
to have a say in everything that the government at every level does,
which would be unwieldy at best, unworkable at worst. In a democratic
republic, the population elects representatives that they trust to
represent their interests, which means the representatives don't always
do what you'd like, especially if they are from the party you didn't
vote for.

The LDG tuners will tune a fairly large range and should work in your application. Look at the QST reviews of a collection of auto tuners for details. Are you using a balanced feedline? If so, you should use a 1-1 or 4-1 current balun to make the connection to the tuner. If you are using coax feed use a 1-1 current balun at the feed point.

Knowing just the SWR does not give you the feed line input impedance which you need to know to understand if the tuner will match. You can use Eznec to tell you the feed point impedance and a program like TLW to model the input impedance and calculate the L and C values for a L network tuner (LDG is a L network tuner). Of course, if you can borrow an analyzer you can just measure it. Depending on the feed line length you may just be unlucky and a change in the feed line length will transform the impedance into something that will match. TLW will help you figure that out.

I use a LDG RT-11 to feed my 136' dipole and it will match on 160 through 10. I use a length of 450 ohm ladder line to a 4-1 current balun to the tuner and of course coax to the radio. I selected the length of the ladder line to insure the match.

Mike, KB3EIA wrote:
"But the idea of signals being actually reflected seems hard to swallow."

It`s true that antennas are measured in degrees. A 1/4-wave antenna is 90-degrees. This is based on how many degrees the signal has changed at the antenna input by the time the signal reaches the tip end of the antenna.

When signal reaches the end of a 1/4-wave whip, there is an abrupt discontinuity. Only displacement current flows without conductors. The tip of the whip accepts only a small fraction of the current available in the forward power traveling on the whip. The only path for the rejected power is back toward the feedpoint. Direction and phase of the current reverse in the reflected power, but the voltages of the incident and reflected waves have the same phase (see 1955 Terman, page 89).

Best regards, Richard Harrison, KB5WZI

==========
99.9 percent of amateurs don't know what their ground connection resistance is. But it's readily easy to determine.

Just erect a random height vertical antenna above the ground connection, tune it, and measure the tuned RESISTANCE between the bottom end and the ground connection using a simple, hand-held antenna analyser. In the tuned condition the antenna input impedance ia always R + j*Zero.

Calculate the radiation resistance of the vertical wire. Deduct radiation resistance plus loading coil loss resistance from the measured value and there you have it.

Loading coil loss resistance is estimated from a crude guess of coil Q. Crude is quite accurate enough if you havn't got a Q meter.

For heights less than 0.3 wavelengths, Radiation resistance can be accurately enough estimated from -

Rrad = Square(24 * Height / Wavelength) ohms

Which is near enough exact when height = 1/4 wavelength.

Measurements need be made at no more than two frequencies, say 3.5 or 7 MHz, and 14 or 21 MHz. This is because ground impedance changes fairly slowly with frequency. And nobody is interested in ground connection resistance above 30 MHz anyway.

What ground REACTANCE may be is neither here nor there because it is not a loss component. In practice it is tuned out simultaneously with tuning up a vertical antenna and merely affects the tuner settings. Ground reactance may be either inductive or capacitative depending on the number and length of radials and on soil resistivity and permittivity. At HF it can be of the same magnitude as the resistive component. But what does a 10-ohm capacitative reactance matter?

By the way, an example of an 'awful' ground connection is a single 4 to 8 feet rod - unless submerged in salt sea water. Depending on the antenna they very often 'work' and, if it's your very first ground electrode, inevitably you will place great faith in it.

Thanks Ivan for your comments. I would like a few more views from amateurs with experience of known ground connection resistance values. Isolated examples, especially with a description of the type of soil, would be especially interesting and useful.

But everybody already knows that 120 radials, of any reasonable length, in any sort of soil is "Excellent".

Yours, Reg, G4FGQ

Then there is the Weimar republic. They managed the voting to
accommodate a political upstart who they installed as chancellor. He
and his cadre brought in their own party faithful to dominate the
function of government, who then jailed, assassinated, or executed
those who installed him. Judges who favored a political climate of
security over individual rights were found and benched so that this
leader could then build special camps for those who were no longer
entitled to their rights of citizenship (due to a possibility of
political terror threat). The enlightened leader then set his army
out to change regimes in other countries so as to allow their citizens
to enjoy peace and freedom from the tyranny and oppression they
formerly slaved under.

There are the illusions of comfort in political labels, thought only
to serve headlines and talk-show topics; and then there are the
consequences where newspapers are neutralized, and talk show hosts
elevated to the minister of propaganda.

The test of history is can you fill in the names alluded to? The test
of freedom is can you pin the mustache on any current Fï¿½rher?

Yes, I did. I didn't know anything about the original question so
I kindly offered to discuss something I know something about. If that
is against netnews guidelines, could you show me where it says so?

> nope, that is a real world situation, but not the one under discussion.

A 1/4WL matching section is not a "real world situation"? Since when?
Everything I post is a real-world situation except for the obvious,
e.g. one-second long lossless transmission lines.

> so which is it, in phase or 180 degrees out of phase???

It depends upon which signal we are talking about and whether the
impedance discontinuity steps-up or steps-down. Assuming the generated
forward wave (a1) has the voltage and current in phase at zero degrees:

For a step-up impedance discontinuity, the s11(a1) reflection term
will have the voltage at zero degrees (and the current at 180 degrees).

For a Z0-match, b1 will be zero so s12(a2) must be equal magnitude
and opposite phase to s11(a1). That puts the reflection from the
load with voltage at 180 degrees (and current at zero degrees).
All interference at port1 is totally destructive for a Z0-match.

The s21(a1) term has voltage at zero degrees (and current at zero
degrees). All interference at port2 is constructive so s22(a2) also
has the voltage at zero degrees (and current at zero degrees).

For a step-down impedance discontinuity associated with a Z0-match,
the phases of the reflected voltages and currents are shifted by 180
degrees and b1 still equals zero.

The above is exactly what happens at the match point at the input
of a tuner. ***Therefore, the great majority of ham radio antenna
systems have the voltages and currents either in-phase or 180 degrees
out of phase at the tuner match point.*** In fact, all a tuner does is
shift the magnitude and phase of the reflected waves from a mismatched
antenna to be equal in magnitude and 180 degrees out of phase with the
reflections from the match point. Therefore, all reflections are canceled
at the match point but not between the match point and the antenna.

This was all explained 64 years ago (when I was two years old) by J. C.
Slater in _Microwave_Transmission_. Why do I have to explain it all over
again?

Richard, you know you are going against the conventional wisdom on
this newsgroup. Ghosting cannot exist during steady-state so if
ghosting exists it simply means that you are still in the transient
state and the steady-state doesn't exist (yet).

There's lots of differences but one is that in a pure
democracy my three-year old grandson could vote on
every proposed law. If you eliminate any citizen from
voting for any reason, it is not a pure democracy.

If your elected representative votes on proposed laws,
rather than you, it is a republic, not a democracy.

Well Richard, here's your chance. Please enlighten us on J.C.
Slater's meaning of: "The method of eliminating reflections
is based on the interference between waves. ... The fundamental
principle behind the elimination of reflections is then to have
each reflected wave canceled by another wave of equal amplitude
and opposite phase."

Looking for the smiley face. It is probably fair to say that in the *general
case* there is no steady reflection in video transmission, unless the round
trip delay is N horizontal lines. BTW, weirdest case I saw came when the dog
chewed through the cable. Now I was seeing the main signal coming from the
cable, plus a ghost that was picked up directly from the transmitter. The
ghost was to the left and above the main signal.

Egads Jim, exactly how much of reality do you think I am capable of
ignoring? Obviously, not as much as you. Why not just say, "God is
the cause of everything I (Jim) cannot explain or understand."?
The meaning would be virtually identical to your present positions.

I *don't* agree with that definition above and your implication that
momentum and energy don't need to be conserved is simply metaphysics
in action. You can argue against energy conservation all you want.
Conservation of Momentum has got you over a barrel in this argument
whether you realize it or not. Somehow, the momentum in the wave
reflected from a mismatched load is reversed. Please explain how
that happens without changing directions. Somehow, the energy in
the wave reflected from a mismatched load changes directions. Please
enlighten us on exactly the mechanism involved. Hint: J.C.Slater
explained it all in _Microwave_Transmissions_ before you were born.

Of course, it is not against the guidelines as the subject was "Reflected Power". I simply continued to talk about reflected power, the subject of the thread. That's a broad subject. Perhaps the originator erred in choosing that broad of a subject but he chose that subject nevertheless. All of my postings to this thread have been about reflected power, including this one, in defense of my postings about reflected power.

> i said it was real world, but it is not what the original thread was about.

The original thread was about "Reflected Power". My example was about reflected power. I might not even have read the text of the original posting. It would be interesting to know why your agenda requires diverting the issue away from "reflected power"? What are you afraid of?

Our club has 2 Telrex beams donated to them and we need assembly and model information. If someone had a scanned catalog that would be a start. We are hoping to use them on FD.

The first is what appears to be a tri-band beam with a tri-band director and driven element with a full size element on 10M and a dual trapped reflector on 15/20m. The matching section is gone so we are looking for details there as well.

The second is a 2 element tri-bander with a matching section in pieces.

I can be reached here or at wb1ehl@nsradio.org

TIA
John / WB1EHL

Is there a smiley face that means, "sad but true"? Many otherwise
intelligent, knowledgeable, educated engineers have attempted to force
their metaphysical "steady-state" agenda on uninitiated and unsuspecting
victims. One is saddened by such an event and one wonders why. Does
a steady-state religion or creed exist within amateur radio? If so,
what are its purpose and goals?

Well then, please enlighten us, Jim. How does nature choose to reverse the momentum in the wave reflected from a mismatched source? It is obvious that the wave reflected from a mismatched source has momentum in the rearward direction. Exactly what reverses that momentum? Please be specific. Remember that standing waves prove that the rearward-traveling wave exists in reality and thus possesses energy and momentum in the rearward direction, both of which must be conserved.

Maybe you should read _Microwave_Transmission_ by J. C. Slater before you continue?

RE: Cecil Moore quote below & 'steady state'

The transmitter is continuously generating incident power, which is continuously subject to reflection(s) by any mismatch in the antenna system. Given the right magnitude, phase and time displacement, each reflection will produce a continuous ghost on the TV screen.

These ghosts can be seen (continuously) in/on the output waveform of a TV demodulator connected at the output of the transmitter -- both in time domain on an oscilloscope, and visually on a monitor. I've seen these continuous reflections scores of times at TV tx sites all over the US as a field engineer for RCA Broadcast Division.

"Conventional wisdom" on this NG may say otherwise, but hopefully some may learn the reality from this exchange.

Hi Hank,

Here's a link which talks about (and illustrates) the physics of waves
at a boundary.

http://www.physicsclassroom.com/Class/waves/U10L3a.html

It shows what happens at the two extremes for transverse waves along a
string - not unlike electromagnetic waves in a transmission line in some
ways. In one instance, the string is fastened directly to the boundary
- a rod in this case. This is analogous to a short across a
transmission line. It will be seen that a reflection occurs, and that
the wave becomes inverted upon reflecting.

In the other case, the string is fastened to a ring which can slide
freely up and down the rod. This case is analogous to an unterminated,
or open transmission line. It can be seen that this too causes a
reflection, only this time the wave is reflected back without a phase
reversal. The amplitude of the reflected wave in both these cases
equals the amplitude of the incident wave.

Now imagine that some friction between the sliding ring and the rod can
be added in varying amounts. This friction would be proportional to the
conductance in an electrical circuit, and would be infinite at one
extreme and zero at the other. The greater the friction, the greater
the conductance (and the lower the electrical resistance). As we begin
to increase the friction (conductance) from zero, the amplitude of the
inverted, reflected wave begins to decrease. The decrease in amplitude
continues with increasing friction until the amplitude of the reflected
wave becomes zero. It could be said that this value is equal to the Z0
of the transmission line.

As the amount of friction is increased still further, a small reflection
once again begins to appear. Only now the phase is opposite from what

it was before. Further increases in friction produce further increases in reflection amplitude until the amplitude of the reflected wave once again equals the amplitude of the incident wave.

What we noticed in the exercise is that there is some value of friction (conductance or resistance) for which no reflection occurs. The exact value depends on the medium through which the wave is propagating. All other values produced a reflection.

There is no perfect explanation, and this certainly isn't a perfect analogy but I hope that it will at least help give you a little more of a feel for the idea.

The definition is accurate as well as descriptive. As I've explained at least a dozen times, energy only moves in the direction of transfer.

Most forms of government can be made to work for awhile if the
people who are supposed to make them work are serious and honest
about what they're charged with doing. Conversely, there is no form of
government that can work for any length of time if it's run by crooks,
con artists, cheap politicians, and hicks.

And it is a very good system indeed! Our system of checks and balances
has done a pretty good job of keeping the country moving on the right path.

Pure democracy has one big problem in that people often vote
emotionally and sometimes upon reflection realize they did so in error.
And of course, a pure democracy can vote to abolish itself! 8^)

Energy moves in whatever direction energy moves. According to
you, if we reflect light energy from Alpha Centauri back to
Alpha Centauri, no energy movement has occurred. Never mind
that it takes 20 years to accomplish that energy movement.
Your "no work equals no energy" concept is as bogus as it
possibly can be. Joules of energy passing a point in delta-
time is power, by IEEE definition.

To me, the threads about reflected power on this NG over the last few days are rather revealing. Some posters quote Terman, Lord Kelvin and others with inapplicable/incomplete statements or formulae attempting to prove (or intimidate) NG readers into accepting that poster's particular point of view -- even when it has been shown by field experience NOT to fit the observed, and measured reality.

Perhaps we should be more willing to further research and modify our favourite, personal hypotheses when valid field experiences show them to be inaccurate.

Actually what has happened, Richard, is that a bunch of engineers and scientists, including gurus on this newsgroup, believe that their math models dictate reality, rather than vice versa. We can thank Einstein, himself, for the following quote:

"One thing I have learned in a long life: that all our science, measured against reality, is primitive and childlike ..." Albert Einstein

Too bad that some people on this newsgroup have adopted their steady-state math models as their unquestioned religion, unrelated to reality.

Unfortunately I can't read all the digressions in the thread. I skim by
author...

This is an interesting twist, Tam. I think if this were the case, then
there would be MORE power dissipated in the Tx than Mr. Fry is saying -
making the situation worse. By that, I mean, getting further from what is
going on. I think this goes in the wrong direction. I believe the flaw is

believing that the Rs=RL must exist for the transmitter.

OOPS! Aluminum oxide, or Alumina, is very non- conductive. It is a ceramic used for as a base high Q circuits at 150 Mhz and above (stripline and microstrip). It is also what is grown on the surface of "anodized" aluminum in the anodization process. It is also why aluminum is so hard to solder. The oxide forms immediately on contact with air. Aluminum is the most reactive metal.

>For heights less than 0.3 wavelengths, Radiation resistance can be accurately enough estimated from -
Rrad = Square(24 * Height / Wavelength) ohms. Which is near enough exact when height = 1/4 wavelength.

Hi Reg, I just went outside and measured the impedance of my 8' mobile antenna. It's center loaded with a high Q loading coil and small capacity hat. It is mounted on a full size pick-up truck. At 7.2 MHZ it reads 37+j0 ohms. The antenna analyzer has always been accurate within a few percent. Does this mean that my truck provides an "excellent ground" at 7.2MHZ? If it does, I need to use my truck for an rf ground for the rig inside my house. It may be that the truck does indeed provide a good ground, I get good results on 40M mobile.

Challenges that the steady-state religion has failed to answer:

How can a standing-wave exist without a forward-traveling wave
superposed with a rearward-traveling wave?

How does reflected wave momentum change directions?

Why does a TDR indicate that reflections actually exist?

What causes TV ghosting in a transmission line if reflections
don't exist?

How does radar work if reflections don't exist?

There is none! The definition is the problem. It is simply a copout.
Sources can dissipate reflected energy. The amount is unknown.

Hi Jack,

It certainly is relevant to ask whether line/antenna mismatch losses are lower with the ATU across all the bands, compared to the ohmic matching of the T2. In any case, nothing is a substitute for getting the antenna up high--but you know this:-)

From what I can see, this is basically a military antenna sold to hams, hence the high price. I think it is pretty reliable for what it delivers, and at 65 feet long, that's a pretty good solution many times. Just get it HIGH up.

Incidentally, I am at W3EF's right now and guest op'ing the night. He typically works EU on 40M in mid-afternoon with 150 watts. Of course, the tower IS at 126 feet....:-)

His option was 3 els linear loaded at 126 feet vs 5 els trapped at 50 feet. I don't think he regrets the decision.

Remember the other added bonus: less neighbor RFI with a higher antenna!

Please make some sort of a technical assertion instead of your
usual metaphysical cagada. Any energy passing a point *is* power,
by IEEE definition.

When you view your reflection in a mirror, do you ignore the
ExB power involved without which you would see nothing?

That's an equality, not a definition. I suspect you're not completely comfortable with the difference in those two things.

> When you view your reflection in a mirror, do you ignore the

I don't notice it until it the resulting chemical reaction takes place on the retina of my eye. Until then, I can only imagine E crossing B, and write the expression for it down on a piece of paper as it has no physical manifestation.

Hi All,

Sorry to intrude with some actual technical content (well I guess this would be twice, what with the mention of the conjugate mirror that stumped Cecil). The reaction takes all of 8 femtoseconds whereas the translation to an electrical signal at a synapse takes the inordinately long time of 1 millisecond.

My correspondent's characterization is:
"One ms roughly the time constant for the production of the first activated intermediate in the transduction cascade, the other steps in the cascade are still slower (for example, the single photon response peaks in about 150 ms in mammals)."

Quantum efficiency is a remarkably high 0.7, easily twice the best instrumentation which barely compares across bandwidth. The transduction cascade that Dr. Detwiler refers to is much like the amplification of a PMT whereby the single photon gives rise to a current of 1000 electrons.

However, to return this to the conjugate mirror; if you looked into one, not one electron would twitch.

At last count there are 130 responses to this post, this is #131, and
the question still hasn't been answered.

When energy or power is transmitted in any medium where the wavelength
and the length of the transmission medium are significant percentages of
one another some energy/power is reflected at any discontinuity in the
transmission medium. The reflected energy/power may be re-reflected if a
discontinuity exists in the backward path.

The simplest example that we can all understand is the common case of
the echo!! H E L L O ! .... HELLO ! .... hello ! .... etc. The
energy/power is re-reflected many times until we can't hear it. But is
is still re-reflecting at sub-audible levels until 100% dissipation
occurs. As long as the discontinuities exist the echoes exist!

I expect that the radiation resistance of your antenna is closer to 10
to 15 ohms. That implies that your truck has a 20 +/- ohm ground system
and your antenna has several ohms of resistance loss.

BTW, that's a typical value of Rr. I measure about the same for my
Ranger on 40 meters.

Here's the scenario:

I'm looking for a portable HF vertical suitable for 'rented cottage' installations. So it must be easily mountable on either the ground, or perhaps bolted to 3 or 4 ten foot sections of chain-link fence rail. (makes a nice temporary guyed mast) It must be easy to put up and take down and put on a roof rack of a minivan.

I would prefer to not need ground radials, although if I use guy wire instead of rope it might work, but not needing ground radials is the preferred solution.

There's usually a heavy canopy of trees overhanging most of the locations, so rotating even the smallest of beams is not an option.

Anyone have experience on this one?

Thanks!
B.

Take a look at the Force 12 portable antennas. 20 -> 10 m. One with a
control cable to switch bands; the otehr you futz manually. I have
tghe version with the control cable. Takes about 15 minutes to put
together nad take down. No radials (it acts as a vertical dipole).

Well the 30 or 40 feet of chain link fence rail is a reasonable start on a low level counterpoise/ground. I guess the question would be, what frequency(ies) are you looking at? Lowwr in frequency, I'd mount at one end. Higher than 30m or so, I would think about putting the vertical in centered on the rail.

And you could place it centered and then hang a few wires off the end to extend coverage as low as needed.

If it's a temporary or portable antenna, you have to work with what you have. BTDT.

Richard

You say my question has been answered but I haven't seen the answer, too old, too stupid, whatever but I still would like to understand. So, would you be kind enough to give me a better understanding of the "mechanism" in the transmitter final that can dissipate and transform yet it can't dissipate a reflection because there's some kind of one way device that acts like a checkvalve or diode that reflects.
tnx

>tnx

Hi Hank,

There is no answer as you phrase the question because the transmitter
does dissipate power reflected to it. I can easily imagine you may
find no understanding as I go hyperbolic in the following lines. :-)

It can also reflect (some or all of) what it does not absorb, but only
if it does not match the line connected to it. The degree to which it
absorbs/reflects is determined by the ratio of its Z to the line/load
at the antenna terminal. In this case (bear with me), the source Z is
NOW found at the load's mismatch, transformed through the line. This
means matching works both ways (often the singlemost ignored aspect of
obvious reciprocity in any of these arguments). Such circuit analysis
is called superposition. This is merely an academic way of saying you
look at the problem from both points of view where you reverse roles
(source becomes load, and load becomes source). This is a common
practice learned in first quarter circuit analysis when Kirchhoff's
laws are developed (Thevenin/Norton equivalent circuits also emerge).

For example (a strained one at that), if you had a 500 Ohm Source
characteristic Z, you will never launch much power into a 50 Ohm
system because it would immediately hit a reflective interface at the
antenna connector. This means that a 500 Ohm source, when confronted
by power going towards it from a 50 Ohm system will reflect most of
that power (but how did we get this power into the system in the first
place - Karma?) This, by design, will never happen in any transistor
ham rig built in the last quarter century.

So, this is why you see such a vacuum of response when you (the
general readership "you") ask:
"What is the source Z if it is not 50 Ohms?"
Silence guarantees they either don't know (a fatal admission for egos)
or if they offered a value, we could all balance the checkbook and

that would end the game being played. Hence we are treated to all these suppositions of shorts and opens or magic reflectors hidden beneath the hood. The frequent toss-off comment of "no one knows" is called projection, a psychological salve for the ego meaning if I don't know, then certainly no one else does either - or they are wrong.

The answer is the transmitter source Z is 50 Ohms at rated power. If a watt of power is chooglin' down the line toward it, that 50 Ohms is going to dissipate into a watt worth of calories. This can be argued with wave mechanics, or lumped circuit equivalents - doesn't matter because it's all the same calories. Modern rigs can tolerate this watt through limited feedback and level controlling circuitry - if you paid more than a kilobuck for your rig that is. For the rest of us, it's a spin of the wheel and you take your chance. 1 watt hardly amounts to much, but are you that lucky that it is ONLY 1 watt? Are we to suppose those unfortunate souls who blasted their rig transmitting into a mismatch lost it only because they lacked enough magic pixie dust? I will bet no rig was lost to a cold snap with frosty finals.

I've already answered about where the heat can be found, so we will conserve bandwidth.

=== WARNING to the logic impaired, the following is a supposition ===

Now, lets simply accept those answers that require the magic pixie dust of total reflection from the transmitter. Fine, the mismatched antenna reflects some power, this power returns to the transmitter, the transmitter simple routes it ALL back to the antenna, round-and-round until the antenna finally radiates it. If this were true, what do we need tuners for? Take a survey of everyone who chants this mantra of the rig reflecting, and ask if they have a tuner in the line. Is it a paper weight holding down their license? Is it a line stretcher because they needed another foot extension between the antenna lead and their rig? Dare I point out the utter failure of their faith?

I will pause to allow those answers to emerge and enjoy the thrashing dawn of a new era of metaphysics. Oooooohhhhhhmmmmms Laaaaaaaaaaw!

Hi all,

I'm considering putting up a 33' vertical - just 3 sections of Rat Shack
mast (solidly bolted for continuity) plus a 3+/- foot 'adjustable' part
on the bottom to 'trim' the length. Then a bunch of in-ground radials.
40m is my only 'serious' band. 15 meters should be a bonus, right?
Or not?

Would this work better than my 4BTV (which I'll keep for 20 and 10)?
Or would the improvement be so insignificant as to not be worth all
the bother of building the new antenna?

Thanks

Dave WB7AWK

==========

Gary, if your coil-loaded 8-feet vertical had been mounted above a ground radial system then the radial system would have to be classified as "poor".

Radiation resistance is about 4 ohms for a height of 8 feet at 7.2 MHz. Coil loss = 3 ohms. Subtract 4+3 from your measured 36 ohms which leaves 29 ohms for the ground loss resistance. Which is a poor value for a radial system. But it may not be poor for your particular vehicle-mounted system because the vehicle itself forms a large physical part of the antenna and so increases radiation resistance.

(The vehicle plus whip behaves as a short, off-centre fed, half-wave resonant vertical, there being fewer ground losses to worry about.)

But the calculating procedure is the same for all vertical ground-mounted antennas. Subtract calculated radiation resistance from measured input resistance to obtain ground loss resistance. If there's a loading coil, subtract its loss resistance too.
Also subtract something for wire-loss of a long wire.

Reg, G4FGQ

Therefore, using your metaphysics, since I live one mile from
where I was born, I can only imagine that I ever worked for
Intel in Arizona.

There is a real world experiment that you can perform to
prove your concepts are incorrect.

TV XMTR--tuner----2 uS long 600 ohm line---75 ohm TV RCVR

The first ghost will occur 4 uS after the primary image.
This can only be explained by part of the energy in the
primary signal changing direction and momentum at the RCVR
and making a round trip to the tuner and back to the RCVR.
In order to make that round trip, the energy in the signal
had to change direction and momentum at the tuner. (There are
no reflections between the XMTR and the tuner.)

Likewise, the second ghost will occur 8 uS after the primary
image, indicating four reversals of direction and momentum
of the energy contained in the second ghost.

By definition, reflected energy dissipated in the source was never
generated in the first place.

RE: Post below

REALITY CHECK: If tx source Z really was 50 ohms, a tx connected to a 50 ohm load would lose 1/2 of the RF power it generates to that internal Z. And if that is true, then the heat produced by the tx, and the AC power consumed by the tx would be proof of that.

However careful measurement of heat production and AC power consumption of broadcast txs (for example) does NOT support the belief that the source Z of a tx designed for 50 ohm loads IS 50 ohms.

Following is the output of an old DOS program I wrote years ago to show operating parameters for a 25kW FM broadcast tx manufactured by my employer, when operating at any RF power and line voltage in its rated range. These values closely track the average of factory test data accumulated over 100s of delivered units.

In this example, if the tx had a 50 ohm source Z it would have to generate 50kW of RF in order to deliver 25kW to a 50 ohm load. In the first place, it doesn't have a big enough power supply or a big enough PA to do that. But even if it could, the input power and heat production would be almost twice the real values shown below.

The same physics applies to ham transmitters, which should be verifiable by an unbiased evaluation of comparable operating parameters.

- RF

* FM TRANSMITTER AC LOAD *

Transmitter name (HT-??FM): ? 25
TPO in kW: ? 25
AC line voltage: ? 220

RESULT:

Total Tx = 103.7 amps/phase, 39.5 kVA total.
H.V. Power Supply Current = 92.7 amps/phase
Total AC/RF Efficiency = 66.5 %

PA Air = 400 cu. feet/min.
Tx Cabinet Flushing Air = 335 cu. feet/min.
Power Supply Air = 250 cu. feet/min.
Total Air = 985 cu. feet/min.

Total Heat = 42810 BTU/Hr.
Heat Rise, total tx system = 39 deg. F.
Air Conditioner Load = 3.6 tons

Dave,
Depending on if the 'old' vertical covered 40 meters at
all, the 'new' vertical might be an improvement. But not
really 'much' of one, there may be no practical difference
in performance on 40 meters.
Would 15 meters be a bonus? If you mean an unexpected
improvement over the 'old' vertical, then, no, the 'old'
vertical probably would work better on 15 meters.
If you don't have the "bunch of in-ground radials" already
in the ground, put them in and then put the 'old' vertical over
them! I think you'll see a greater over-all improvement that
way, rather than with just the 'new' vertical (except on
40 meters, maybe).
"Full sized" antennas work 'better' than 'shortened'
antennas,
in general, but sometimes that 'better' is sort'a hard to hear.

Richard
This is in response to your answer of last night. Before going to bed I got out the book REFLECTIONS II by Walt Maxwell W2DU. I'm typing verbatim from page 2-2 and 23-1 for those who don't have the book.page 2-2 "Contrary to what many believe, it is not true that when a transmitter delivers power into a line with reflections, a returning wave sees an internal generator resistance as a dissipative load. Nor is the reflected wave converted to heat and, while at the same time damaging the final amplifier....the reflected power is entirely conserved...." from page 23-1 "One of the most serious misconceptions concerned reflected power reaching the tubes in the RF amplifier of the transmitter. The prevalent, but erroneous thinking was that the reflected power enters the amplifier, causing tube overheating and destruction. However, I dispelled this misconception in the above mentioned publications, using wave-mechanics treatment, discussed here in greater detail, by showing that when the pi-network tank is tuned to resonance, a virtual short circuit to rearward traveling waves is created at the input of the network. Consequently, instead of the reflected power reaching the tubes of the amplifier, it is totally re-reflected toward the load by the virtual short circuit appearing only to waves at the network input".
I'm guessing it's a virtual short because the pi-network is resonant but what happens if it is a bit off. Also what happens in a transistor final with no pi?

2858. Reflected power ? new thread, new beginning, kinda ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-25 13:57:58 UTC
From: Henry Kolesnik <kolesnik@sbcglobal.net>
Message-ID: <GhIsc.431$zG3.320@newssvr24.news.prodigy.com>
Source record: 94563

The previous thread got too big and convoluted for me so I started another if for no other reason than my own clarity and convenience. It's still the same question "I know that any power not dissipated by an antenna is reflected back to the
transmitter. Then the transmitter "reflects" this reflection back to antenna, ad nauseum until its all gone. I also know that a short or an open is required to reflect power and I'm searching for which it is, an open or a short. I'm inclined to think it's a virtual open but I'm at a loss to understand that and I wonder if someone has a good explanation or analogy and some math wouldn't hurt".

Before going to bed I got out the book REFLECTIONS II by Walt Maxwell, W2DU. I'm typing verbatim from page 2-2 and 23-1 for those who don't have the book.

Page 2-2 : "Contrary to what many believe, it is not true that when a transmitter delivers power into a line with reflections, a returning wave sees an internal generator resistance as a dissipative load. Nor is the reflected wave converted to heat and, while at the same time damaging the final amplifier....the reflected power is entirely conserved...."

From page 23-1 "One of the most serious misconceptions concerned reflected power reaching the tubes in the RF amplifier of the transmitter. The prevalent, but erroneous thinking was that the reflected power enters the amplifier, causing tube overheating and destruction. However, I dispelled this misconception in the above mentioned publications, using wave-mechanics treatment, discussed here in greater detail, by showing that when the pi-network tank is tuned to resonance, a virtual short circuit to rearward traveling waves is created at the input of the network. Consequently, instead of the reflected power reaching the tubes of the amplifier, it is totally re-reflected toward the load by the virtual short circuit appearing only to waves at the network input".

I'm guessing it's a virtual short because the pi-network is resonant but what happens if it is a bit off. Also what happens in a transistor final with no pi?

Henry,
Here is an example of what you just said. Take a sine wave source, and
connect it to a 1/4 wave section of shorted transmission line through a
series resistor R. The reflected wave will reach this resistor 1/2 cycle
later, and will be in phase with the source. For a lossless transmission
line, there will be *0 Volts across the resistor*. There will be 0 current
through the resistor, and the reflected wave will be re reflected for all
values of R, including R=Z0, because the reflected wave will not "know" what
R is. You can get the same answer from knowing that the impedance looking
into a 1/4 wave section of shorted transmission line is infinite.

Nope, I wouldn't. But that seems to be what some people
are saying. I objected to that definition about 15 years
ago. I was asked to prove otherwise and was unable to
do so. The generated power is *defined* as the *net*
steady-state output power of the source.

That's why many of my examples involve signal generators
equipped with a circulator and load, outputting a constant
forward voltage in phase with a constant forward current.

That describes a Class-A amplifier.

With other classes of amps, the amplifier's individual component signals
are non-linear.

The more you talk about 'steady-state-, the more apparent it becomes that
you don't really understand what it means.

Please note that when this was written, there were no solid-state transmitters
with fixed 50 ohm outputs. Walt was talking specifically about tube transmitters
with built-in adjustable pi-net antenna tuner circuits, like my old Globe Scout.
The closest present-day transmitters to match the above statements would be
something like my IC-756PRO with a built-in auto-tuner.

> I'm guessing it's a virtual short because the pi-network is resonant but
> what happens if it is a bit off.

If it is a bit off, reflected voltage and current flow into the finals
and superpose with the source voltage and current. Since the reflected
voltage and current are 180 degrees out of phase, the superposition
usually causes the load on the amp to become reactive. Even if the
voltages are in phase or the currents are in phase, the load on the
amp becomes something other than the designed-for load. The result
can be over-voltage or over-current or both. That's not good.

> Also what happens in a transistor final with no pi?

Note: most transistor finals have a fixed pi-network designed to
operate into a fixed 50 ohm load. The results would be the same as
the detuned example above. Such commercial finals are protected
from over-voltage and over-current by decreasing the source power.

Very familiar stuff which I have held Walt accountable for. We have
had considerable correspondence to this point and he is holding my
argument in suspension, pending his bench work confirmation of my
simple experiments that I have posted here to this effect.

>I'm guessing it's a virtual short because the pi-network is resonant but
>what happens if it is a bit off. Also what happens in a transistor final
>with no pi?

What you describe is consistent with Walt's language, you deserve
points for following his logic. As for your question about the
transistor final with no pi network. That was handled quite
explicitly by me for the thread "Loop Antenna for Class-E amplifier"
in correspondence with Toni, ea3fya and Marc Battyani. If you will
note, this thread was entirely devoid of ego so puffed up in these
issues, and we had the rare opportunity of a third, independent
observer who also sat at the bench and followed the instructions and
comments I offered with actual construction and testing to POSITIVE
results. You may also note the absolute vacuum of other's comments
imploring that his data was chimerical, illusions of a meter. In fact
it was one of those rare threads with a question much like yours, with
the same simple observations offered by me, confirmed and ending in
very much less than 600 postings of supposition and superstition.

However, back to Walt's treatise and your reading of it. I again
simply ask: "Do you have a tuner in line each day you fire up your
rig? Why, if you have faith in your logic, do you need it?"

As I've pointed out, there's the recent thread, and any number of
simple tests and experiments that I have offered here. These etudï¿½s
are typically ignored in favor of vacuous theory-spinning - NONE of
which answer the simple question: "What is the Source Z if it is not
50 Ohms?"

Dear Richard,

This is the time-honored misreading and misapplication of Thevenin's
theorem posed by Edison to confound investors in Westinghouse's AC
generation plants. Look at the ratio of DC to AC power plants
constructed in the past century to find the poor accuracy of your
reading.

> and some math wouldn't hurt".

Hank, Here's what happens at the match point in an amateur radio antenna system. Walter Maxwell himself references J. C. Slater's book.

From _Microwave_Transmission_, by J. C. Slater: "We can get a better understanding of (matching) devices by considering reflections at discontinuities. This method is useful in considering any impedance-matching device, and we shall think of it first in connection with the ordinary quarter-wave transformer. The object of this transformer is to eliminate the reflection that would be present if the impedance Z1 were connected directly to Zt."

The diagram is: Z1----1/4WL Z0----Zt where Z0 is a 1/4WL transformer section that matches Z1 to Zt.

"The method of eliminating reflections is based on the interference between waves. Two waves half a wavelength apart are in opposite phases, and the sum of them, if their amplitudes are numerically equal, is zero. The fundamental principle behind the elimination of reflections is then to have each reflected wave canceled by another wave of equal amplitude and opposite phase. In order that this second wave may have traveled half a wavelength farther than the first, it is obvious that it must have gone a quarter wavelength farther up the line, and correspondingly a quarter of a wavelength back, before it meets the original reflected wave. In other words, two discontinuities in characteristic impedance, of such magnitude as to give equal amplitudes of reflected waves and spaced a quarter of a wavelength apart, will give no net reflection and hence will not introduce reflections into the line."

Here's how to perform an experiment to answer your questions. The source (SGCL) is a Signal Generator equipped with a Circulator and Load. It puts out a constant 100 watts. All reflected power is dissipated in the circulator load.
very short

100W SGCL---50 ohm line---tuner----------450 ohm line------------Load

Initially, the system is tuned for a match so there are no reflections on the 50 ohm line. Then the load is changed to 450 ohms. Assuming the load was not 450 ohms to start with, this will cause reflections to appear on the 50 ohm line. We can use an oscilloscope to measure the magnitude and phase of the voltage across the 50 ohm circulator load resistor. That's the reflected voltage. We can calculate the reflected current through the 50 ohm circulator load resistor. So now we have the component voltage and current reflected from the input to the tuner. We can reference the phase of the reflected voltage and current to the phase of the source voltage. Let's say the source voltage has a reference phase of zero degrees.

Assume we measured a reflected voltage of 30 volts at 10 degrees and calculated a reflected current of 0.6 amps at 190 degrees. (Note that the reflected current is always 180 degrees out of phase with the reflected voltage.)

Now switch the load from 450 ohms back to the original load. What happens at the tuner input to achieve a match is the superposition of two reflected waves. We know what the first one looks like so we deduce what the second one looks like.

The first reflected wave, reflected from match point at the tuner input is:

30 volts at 10 degrees and 0.6 amps at 190 degrees

The second reflected wave, returning from the load and reaching the match point at the tuner input is:

30 volts at 190 degrees and 0.6 amps at 10 degrees

Adding those two voltages yields zero volts. Adding those two currents yields zero amps. Thus the match is accomplished.

What the tuner does is shift the magnitude and phase of the voltage and current reflected from the load to cancel the reflection of the source wave that occurs at the input of the tuner.

The reflected voltage flowing toward the source is canceled to zero through superposition of the two reflected voltage waves.

The reflected current flowing toward the source is canceled to zero through superposition of the two reflected current waves.

That's how all matching devices work according to J. C. Slater.

Hi Richard,

This quote above bears directly to one of my observations. You define
by negatives, and that is a shoddy technical discussion worthy of the
creationist argument.

Tell us what it IS instead. A simple complex number is all that is
asked, derived from actual measurement. I've done this numerous
times, and not simply for milliwatt signal generators and have
returned these readings to the client with certificates of
traceability to Primary Standards Labs.

Barring any explicit answer that yields this complex number; then that
answer is simply conjecture and illusion that is commonplace in this
discussion. Draping it with programs and formula doesn't give
substance to the shape of that dream.

2874. Tx Source Impedance & Load Reflections

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-25 16:23:03 UTC
From: Richard Fry <rfry@adams.net>
Message-ID: <2hha6pFcsms8U1@uni-berlin.de>
Source record: 94577

This topic deserves more attention than it will get from its previous placement deep in some recent threads.

Below is a quote from a paper titled "A Study of RF Intermodulation Between FM Broadcast Transmitters Sharing Filterplexed or Co-located Antenna Systems," by Geoffrey Mendenhall. Mendenhall is a registered professional engineer, and now a VP for Harris Broadcast Division in Mason, OH. He is responsible for the engineering research and design of the entire transmitter product line: AM, FM & TV.

This paper and quote has to be read here with some interpretation, because it is an analysis of what happens when an in-band signal from one transmitter is coupled into another transmitter when their antennas are close together and/or when adequate filtering of the external signal is not provided. But it is strictly applicable also for single tx and antenna systems, where an antenna mismatch produces reflections back toward the transmitter. In this case the "interfering signal" is not external, but a reflection of the incident power of that tx.

QUOTE: Output return loss is a measure of the interfering signal that is coupled into the output circuit versus the amount that is reflected back from the output circuit without interacting with the non-linear device. To understand this concept more clearly, we must remember that although the output circuit of the transmitter is designed to work into a fifty ohm load, the output source impedance of the transmitter is not fifty ohms. If the source impedance were equal to the fifty ohm line impedance, half of the transmitter's output power would be dissipated in its internal output source impedance. The transmitter's output source impedance must be low compared to the load impedance in order to achieve good efficiency. The transmitter therefore looks like a voltage source driving a fifty ohm load. While the transmission line is correctly terminated looking toward the antenna (high return loss), the transmission line is greatly mismatched looking toward the output circuit of the transmitter (low return loss). This means that power coming out of the transmitter is completely absorbed by the load while interfering signals fed into the transmitter are almost completely reflected by the output circuit. END QUOTE

The transmitter topology in this study was a single PA tube operating Class C. For these designs, an on-carrier return loss value of 2dB or less is rather common. At 2dB the reflection coefficient is over 79%.

PAs comprised of multiple devices combined by balanced methods (e.g. 3dB hybrids, Wilkinsons) can provide a source impedance closer to 50 ohms (higher return loss). In these cases, power that is reflected off the load and NOT re-reflected by the tx mostly is dissipated in resistive networks in the PA combiner. However these networks do not provide a load for the

forward power from the tx, only for reflected power from the output termination.

Ever measure the forward and reflected currents halfway into a
shorted 1/4WL stub? How can currents be flowing unimpeded into
and out of an infinite impedance? Hint: it's the net current
that is zero at the input of a 1/4WL stub. The forward current
and reflected current are equal in magnitude and opposite in
phase. Their individual magnitudes can be very large.

Hi Hank,

I used to teach this Collins equipment in the Navy. I presume yours
had a finals tuning circuit still in it? Hard to imagine it
otherwise.

Tubes are different from transistors only by approaching the Source Z
with an inverted ratio of transformation. Ever hear of plate
resistance? It is literal resistance. Ever see a plate glow when
under the stress of hi SWR? It is literal heat. The same heat is
generated irrespective of it being explained by wave mechanics or
lumped equivalent circuits. Choose the model you are comfortable
with, and then tackle the SWR if you care about efficiency.

If anything, tube sets prove the problem of reflected power through
your ability to directly observe the heat generated and experience the
cost of new finals tubes through their degraded life span. This stuff
is all rote teaching; and my students were given practical tests to
troubleshoot, tune, and repair against such scenarios.

I've had hands-on experience with this topic both academically and at
several benches - the sophistries that deny these points are amusing,
but remain amateur scribblings.

Richard,
Is there a description somewhere that details which losses in an amplifier have an effect on the output impedance? For example, the fairly high parallel equivalent collector resistance would manifest itself as a fairly low value series output resistance. There are other collector and emitter losses that would have an effect on output impedance. What happens to the ~30% loss inherent in a class B amplifier? Is that a DC loss?

Source record: 94581

The source Z of a typical tx having a single-ended Class C PA is just a few ohms. The exact value depends on circuit design and tuning adjustments. Heavy loading of the output tuning network of the PA reduces the return loss looking back into the tx, and lighter loading improves it.

Please read my post using the new subject line "Tx Source Impedance & Load Reflections" that I started for this a few minutes ago. The paper I refer to and quote there (not mine) is accepted in the broadcast industry as a benchmark on this subject.

Which is a creationist-model of negative definition.

This is poor substitute for expressing a simple complex value derived
from actual measurement. The methods for accomplishing this are rote
material practiced by designers every day. The quality of their
product is in proportion to the accuracy of their determination.

Source record: 94590

I know free space half wave dipole length in feet is 492/f mhz.
I also know 468/f mhz is for "antenna cross section...stray
capacitance...called end effect because the ends of the antenna are
made farther apart electrically than they are physically..." as laid
out in the "Practical Antenna Handbook 3rd edition p.138".

This is suspiciously close to the 95% velocity propagation of parallel
line.
My question is, for a given coax with 66% velocity propagation, is the
formula 66% of 492 (325/f) or
66% of 468 (309/f)?

Thanks in advance

I hate this reverse posting, so I'm changing.

First Henry (Thinks for the swell phone conversation) has the idea in basic form:

> Henry Kolesnik wrote:
>
> > [...snip...] "I know that any power not dissipated by an antenna is
> > reflected back to the
> > transmitter. Then the transmitter "reflects" this reflection back to
> > antenna, ad nauseum until its all gone.
> > ....I'm inclined to think it's a virtual open but I'm at a loss to
> > understand that and I wonder if someone has a good explanation or
analogy
> > and some math wouldn't hurt".

Hank uses the term "virtual open" a rather loose term but a good model, however, keep in mind that he is talking about a system with NO "matching device" as we call it, just a transmitter. He is also talking about the REVERSE DIRECTION where all the power gets reflected back to the load and we all live happily after. (the same concept applies for a matching device, as well)

Then in a longer version, Cecil quotes (see below), but he is referring to a matching device. He is also directing his attention to the forward direction, unlike Hank above, and he moves to the matching device's input. What the concept here is, concerns what the forward wave sees at the matching input so that there is no net reflected power. The concept is this:
One wave from the transmitter (call it wave "A") hits the matching device. Some makes it through toward the load and some is reflected back toward the Tx due to the matching device's weird impedance...HOWEVER, the wave coming from the load has some component which makes it through the matching section to the input (call this wave "B"). It is wave "A" abd wave B"B which must be equal in amplitude and 180 degrees out - therefore cencelling for a net wave back toward the Tx of null, naught, zip..all is happy in the world of ham radio

--
Steve N, K,9;d, c. i My email has no u's.

P.S. Get this MPT blockage out of your minds... The "maximum power therom" (ZL=Zs) ONLY applies to ONE special case, NOT all cases. That case is where the source's output power (or if you like current) capability is limited ONLY by the two resistances. That is, the case is when the source can put out all the power needed by these resistors and no other internal limit

dominates. A common circuit can be shown to give maximum power at other
than Zs=ZL (aparently violating the above referred-to therom). There are
things other than these resistances that limit the output power of a
practical source.... (see how long this thread goes.....

In the case of a lossless, 1/4WL stub, (no such thing, except on this newsgroup) in the steady state you can disconnect the transmitter and the currents will still be there. Current doesn't flow, Cecil, charge flows. Current is just the rate of flow of charge, dQ/dt. In a 1/4WL stub, charge, and the fields associated with it, are in a state of oscillation. Over time, their average movement in space is zero. It's too bad you have to think of current
as like the water in a big river that has to flow from one place to another in order to exist. (That's wrong, too. Current in a river is the rate of flow of
water past a point, not the water itself.) Sloppy semantics sure screw up understanding.

Source record: 94597

Gee what are these "feet" things? <grin> (I use 300/f for free space - for metres)

Velocity factor in coax is vs free-space. If you are using these numbers for calculating tuned lengths keep in mind that the manufacturing tolerance for velocity factor is not real accurate and you should cut/tune with a GDO/TDR etc.

From my reading I have seen dipole end effect vary between 90 and 98%. Almost always a function of length/diameter ratio.

Cheers Bob VK2YQA

2890. Re: Reflected power ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-25 19:43:42 UTC
From: Henry Kolesnik <kolesnik@sbcglobal.net>
Message-ID: <OlNsc.559$Ef5.375@newssvr24.news.prodigy.com>
Source record: 94594

Good points, my 30S-1 has load and tune still in it and the final a
3CX1500B is ceramic and can't be seen but it never lost it's Eimac stencil.
However my Collins 30L-1 was a different story. Once or twice I had 811As
with holes melted in their plate structure. They continued to work well and
I always thought this was from overdriving but now I'm not so sure because
it ran at the same high swr as the 30S-1. I used the 30L-1 in summer
because the air conditioner couldn't keep up with the heat generated by the
30S-1 so it was my winter amp.
I notice that Walt Maxwell's Reflections II was published by World Radio
whereas Reflections was by the ARRL. There is some disagreement on
"conjugate match' and probably other things between ARRL and Walt. So now I
have to wonder if the final tube is dissipative or non-dissipative for
reflections.

Looks like my new thread isn't working but I'm posting this to it just in
case since I don't really know the customary protocol on a long thread that
sometime digresses.

Richard Clark has some good points. My 30S-1 has load and tune still in it and the final a 3CX1500B is ceramic and can't be seen but it never lost it's Eimac stencil. However my Collins 30L-1 was a different story. Once or twice I had 811As with holes melted in their plate structure. They continued to work well and I always thought this was from overdriving but now I'm not so sure because it ran at the same high swr as the 30S-1. I used the 30L-1 in summer because the air conditioner couldn't keep up with the heat generated by the 30S-1 so it was my winter amp. I've seen 3-500Z and 4-1000 plates running red hot but I think it was from overdrive and not SWR but really wan't paying enough attention, I wish I had.
I notice that Walt Maxwell's Reflections II was published by World Radio whereas Reflections was by the ARRL. There is some disagreement on "conjugate match'" and probably other things between ARRL and Walt. So now I have to wonder if the final tube is dissipative or non-dissipative for my reflections and not Walts. Pun unavoidable.

Looks like my new thread isn't working but I'm posting this to it just in case since I don't really know the customary protocol on a long thread that sometime digresses.

Yep, you got it! J. C. Slater stated such in _Microwave_Transmissions_
before most present day hams were born. I'm glad you understand.

Since that configuration doesn't exist in reality, only God
can cause what you are asserting. Why am I not surprised that
you need a supernatural being to prove your arguments?

> Current doesn't flow, Cecil, charge flows.

:-) :-) Having to resort to trivial arguments is the sure sign
of a loser. :-) :-)

Tac wrote:
"My question is, for a given coax with 66% velocity propagation, is the formula 66% of 492 (325/f) or 66% of 468 (309/f)?"

VF, velocity factor, is % of the free-space velocity of a radio wave which is identical to that of light.

Velocity of light is about 300,000,000 m/sec.

Wavelength in free-space is:

WL= 300,000,000 / f meters

There are about 3.28 feet in a meter.

Polyethylene insulated flexible coax cables usually have a velocity of propagation of about 66% that of free-space. Velocity depends on cable dimensions as well as its insulating material and distribution.

In my ARRL Antenna Book, the length in feet for a 1/2-wave dipole is given as 468/f (MHz).
As 1/2-wave= 150/f (MHz) x 3.28 ft/mtr=492/f (MHz), it is clear the handbook formula has been discounted by 5% for "end effect", which is actually a function of how fat the wire used is, and relates to wave velocity reduction.

Best regards, Richard Harrison, KB5WZI

2899. Re: End effect, velocity propagation question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-25 21:00:04 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10b7cuo3m6bi420@corp.supernews.com>
Source record: 94604

A half wavelength in a transmission line with velocity factor of 66% is approximately 0.66 * 492/f(MHz).

Here's why. Wavelength = v / f where v is the velocity of electromagnetic waves and f is the frequency in Hz. v = c * vf where c is the velocity of light in free space and vf is the velocity factor. The velocity of light in free space (c) is approximately 984,000,000 feet/second. So one wavelength, in feet, in any medium is approximately 984,000,000 * vf / f(Hz), or 984 * vf / f(MHz). A half wavelength is then half of this, or about 492 * vf / f(MHz) feet.

A resonant "half wave" antenna is always shorter than a free-space half wavelength for a variety of reasons. Its actual length depends on wire diameter, end insulators, the effect of ground, and so forth. 468/f is a useful approximation that's usually in the ballpark but seldom exactly correct.

Roy Lewallen, W7EL

Hi Hank,

Those pinholes (or larger) that you found in the plates occurred by a
very fascinating display of plasma. If you are really putting the
hurts to it, you will observe a football shaped plasma between the
plate and the cathode where the point terminates (and penetrates) in
the enlarging ruby glow of the plate. This is visible in some tubes,
not others, depending of course on tube structure. I've had students
point out tubes still operating with the glass envelope completely
melted (or jelled rather) and collapsed, hugging the structure!

Hence you have confirmed the dissipation of return power directly -
all mumbling aside from theorists who describe it as virtual. ;-)

As for Walt's publishing house shift, I don't recall him having any
technical issue, but I let that go as he found another outlet and got
to say what he considered was important. I proofed a number of his
appendices and we corresponded quite often about our differences. To
his credit, although I dispute his stand, he maintains an open mind on
the subject and offers he will look into my experiments that reveal
this. He has already measured the value of 50 Ohms, the point of
departure between us is whether this same value absorbs power.

So, you see, you get numbers from those that sit down to the bench and do it, you get pixie dust from the rest.

And as for new thread or old, this topic has run to 600+ postings in years past; so opening it as a new topic is fine to allow news readers (like mine) from pushing the indentations out to the event horizon. This post is not so deeply nested though.

Its "tripping" Mike ? Ive studied the schematics and its a little beyond me, normally |I can suss most faults out but this one is a right pig. I have totally disconnected the PSU from the rest of the radio and on switch on it will just sit there and produce 13.5 and 24v but you put a load on the 24v output and it seems to trip and you have to disconnect the mains and leave it for a while or discharge the caps until it will work again. In the rig, with it all wired correctly, you wind up the power and again it trips and you have to leave it to "reset" ???
Can anyone shed any light ?
If anyone wishes me to send them a file of the PSU schematic then please let me know.
Thanks.

well, the direction could be by a small pair of crossed loops, plus a
polarity sensing element to remove the directional ambiguity. add a small
flux sensing element to determine the orientation of the sensor and there
you can get a magnetic bearing. the polarity sensing element can also
generate a peak amplitude signal which can be used to make a very rough
estimate of distance. add a couple digitizers and a fancy map program and
you have it made.

Hi OM,

A simple design would be to connect each loop into the vertical and
horizontal channels of an O'Scope (one loop replacing the Time Base).

When you do this with signal sources, you get Lissajou patterns. Same
thing, more or less, when you get a lightning strike. The lobe of
excitation (an elongated loop) will point in the relative direction of
the strike (once you calibrate it, and consider you could be off by
180ï¿½). The larger the loop, the closer the strike, so there is an
inverse relationship to consider too.

This was a subject of a Popular Science article in the 60s.

Hi Hank,

A little follow-on, if you will. I presume you tuned into the load
first before switching to the antenna. How did you determine the SWR?
Were you driving a twin lead transmission line going to your
mismatched antenna, or a coax?

The "transform along the coax" part is correct, but the "power is
maximised" part can be VERY misleading folks.

P.S. Get this MPT theorm blockage out of your minds... It is a synthetic
restriction.
The "maximum power therom" (ZL=Zs) ONLY applies to ONE special case, NOT
all cases. That case is where the source's output power (or if you like
current) capability is limited ONLY by the two resistances. That is, the
case is when the source can put out all the power needed by these resistors
and no other internal limit dominates. A common circuit can be shown to
give maximum power at other than Zs=ZL (aparently violating the above
referred-to therom). There are things other than these resistances that
limit the output power of a
practical source.... (see how long this thread goes.....

I use a Fluidmotion BiggIR vertical on a 3500 ft^2 aluminum roof. The house
is on a hill in the country.
Works great on 40. I really like it. The DX at 3AM (that is just not there
on a dipole) is LOUD.
I can use it as a 3/4 or 1/4 on 15 and can't tell much difference.
Sometimes one is better, sometimes the other. Propagation can be complex.
Nice to be able to push a button and see which is best.

Electromagnetic waves can cancel, but rocks can't. Could that maybe
make a difference?

Hi Jim,

This is like mistaking electrons and charge displacement. Sound like
Ed described two rocks hitting with an inelastic collision which
results in power dissipation.

The IEEE Dictionary shows the relationship between energy passing a point and the equivalent in units of power. That is a fact.

Proving that reflections actually exist, and that when all you have is a hammer, everything looks like a nail. Are you trying to prove something, or disprove it with your ghost story? You're not generating a clear picture. ;-)

Boy, I'm gonna have to try and find my old EE5xx Non-Linear Transistor Design notebook. I doubt I could translate it into words for this section of the thread, but it is incredibly applicable.

I took it not knowing what it really was - RF amplifiers, tank circuits and matching circuits of every flavor, and how much DC power was used and RF delivered at the primary freq and all harmonics. He also covered doublers, triplers, phase locked loops (from scratch), the whole 9 yards. I learned more in that one class than in any other 5 I took. The professor was fantastic and very very tough. It was also the most demanding course I ever took.

I used 450 ohm ladder line and a balun along with a cheap SWR meter.

It will still be quite usable for "average" use. Maybe not as good as
a shorter vertical at low angles, but he wouldn't have trouble making
contacts with it. My 40/17 GP worked pretty well on 15m, despite the
increased average angle of radiation. It was lame as heck on 12 and 10
though...No doubt about it...MK

It'll be better on 40m. No doubt. Hard to say on 15, but you might be
surprised. I don't think it would be quite as bad as some forecast.
For average use anyway.
You might consider 17m as a 5/8 wave. Easily matched with a series
loading coil at the base. Of course, you would want to take it out for
40m, unless you want to be tuned at 6.9 mhz...:/ I used a 24 volt
relay to switch on one antenna I used. MK

Hi Tom,

It's not that difficult. Edison corrupted the Thevenin model
demanding that there be a RESISTANCE equal to the load to accomplish
this equivalency (a case of being overly literal for a market
advantage). The Thevenin model only requires an IMPEDANCE, hence
these allusions to 50% maximum efficiency (an imposed condition much
like debate here) were an invention by Edison to detract investment
away from AC power transmission and attract it back to his DC dynamos.
The real pro's new how to dance with numbers and concepts too.

This resolves how the common Ham rig can present 50 Ohms Impedance and
still offer more than 50% efficiency - although, a simple examination
of the power in vs. the power out reveals it isn't nearly as good as
50% for ANY mode. Such is the gulf between reality and theory - some
folk's mileage may vary. ;-)

You could also try Aldrich chemical http://www.sigmaaldrich.com search by Molecular Formula for "Na" and you'll find an assortment of offerings of the metal. Download an MSDS for it first! It can be nasty to deal with. A bucket of Class D (Metal Fires) extinguishing agent or a Class D fire extinguisher can come in handy too, check Ansul http://www.ansul.com for MET-L-X or NA-X extinguising agent!

Must have never worked w/ Sodium, NaK (sodium- potassium alloys, usually liquid phase at room temperature) or Lithium-Aluminum alloys. Never had the pleasure to work w/ pure Li but I'd guess it is entertaining to say the least.

Aluminum is quite reactive, fortunately aluminum oxide is quite stable, and usually forms quickly, quietly and uneventfully.

Scotchbrite pads would be better than steel wool to clean it up.

To clarify
a) "Load" in my context means "load resistor (r) and load capacitor (reactance

jx) in series"
b) The output transistor feeds to the output port through an inductor. One would therefore expect X, the source reactance, to be positive.

This is absolutely the best thread I've seen in years. It's educational, thought provoking, entertaining, and revealing about the human psyche.

The thread reminds of some of those that I monitor from time to time regarding aeronautics and fluid dynamics on the topic of how an airplane wing generates lift. Believe or not, there is still no consensus after 100+ years. It's interesting in that it parallels this thread in many ways -- attempting to interpret various abstract mathmatical definitions of a physical process in a way that it "makes sense." We're fortunate in that such things don't actually have to make sense to work.

My recollection from my high school chemistry days is that sodium
doesn't catch fire in water, just bounces around and fizzes
vigorously. Potassium metal, OTOH, does catch fire as it fizzes and
bouces around even more vigorously.

I had such fun in the chemistry lab.

Hi Hank,

I gave this some more thought from my Collins period. If I recall,
overdriving an amplifier brings damage to the grid, which has its own
dissipation limit. The usual failure mode is that it melts or sags
and causes a grid-cathode short. This is especially true in
lighthouse style tubes.

Hi, all concerned:

If the analogy holds:

R-f transmission-line swr reduction by what ever means is, I think, akin to what the local power company accomplishes by hanging lumps of reactance across its a-c transmission lines, ie, reducing volt-amps-reactive, in its system.

Picture an alternator delivering rated current into a reactance:
I-squared-R is, I think, dissipated in the resistance of the alternator windings.

No wonder an anode glows *in some cases* due to "mismatch".

If the analogy holds.

So, one fine day, I'll test this hypothesis: I'll fire up a 4-400 (no ceramic jugs allowed!), on some h-f band, driving it to (metered) d-c input levels just below its rated dissipation, into a mismatch built like a battleship in its plate circuit.

(How) Is it possible with metrology (that I can afford, much less obtain use thereof), for me to know without a reasonable doubt what the proportions of plate-glow due to little-r-sub-little-p and "reflected power from the mismatch" are?

Are there other sources of plate glow?

Is there a homebrew instrument that I can make that will let me know when
I'm out of the near field and in the far field? I'd like it to work with
mobile whips as well as dipoles on HF. The ARRL Ant HBK formula for the
boundary D between the two fields is an approximation where D = 2L^2/w where
L is ant length in same units as w, the wavelength.
tnx

Hello!

My question is:

When should I use Vigants or Lenkurr or ITU-R Rec. models in my RR
Budget calculations. Who of those models is best for planning and how?

Best regards, and thank's for replys!

AK.

Side Comment:

Unfortunately, Richard Clark, the essence of your comment is completely lost on me. I haven't the faintest idea what you mean. Are you criticizing the quote or supporting it? Whatever...

Real content:

The quote posted by Richard Fry certainly explains well what we call "Transmitter IM'" (the PA is a mixer and Tx frequencies mix producing other signals). In the cellular telephone base station transmitter we have up to 20 transmitters on one antenna. In this case the IM is much more serious because the power of the undesirable transmitter is not from a near antenna, but a transmitter directly connected to the same antenna. Circulators in each transmitter output are required to reduce the IM to acceptable levels by diverting the unwanted TX signals to a load instead of the PA device..

I believe his intent (I'm guessing) is to show an authoritative report that the output Z of a power amplifier is not equal to the load or transmission line impedance, right?

As I stated before (with spelling corrected):

Get this MPT theorem blockage out of your minds... It is a synthetic restriction.
The "maximum power theorem" (ZL=Zs) ONLY applies to ONE special case, NOT all cases. That case is where the source's output power (or if you like current) capability is limited ONLY by the two resistances (source and load). That is, the
case is when the source can put out all the power needed by these resistors

and no other internal limit dominates. A common circuit can be shown to give maximum power at other than Zs=ZL (apparently violating the above referred-to theorem). There are things other than these resistances that limit the output power of a practical source.

I add... In fact, in that quote, he comments that a low source impedance is what makes for higher (>50%) efficiency.

The sum of the loads on a power line is virtually always inductive
so the power company adds capacitors where they are needed. That is
akin to stubs on an RF transmission line. Guess how long a 1/8WL stub
would be at 60 Hz. :-)

Nice attempt at an analogy (and capitalization), but this is not what happens in the t-line case. If it were, (or is it 'was') the power would all be heating the coax and it is not. Each time it gets to the load, some more makes it to the load until it all gets there.
Steve

Hi Richard,

Not if it is strictly resistive. This is the rhetorical dance of conditions. Too many arguments turn on a resistive load, and then demand efficiency in terms of a resistive Thevenin model. That just doesn't pass.

Of course, it works for the purely resistive.
R+j0 is the conjugate of R-j0
